On the basis of findings in studies of the pathological processes involving the peripheral auditory organ, *Sporleder* (1899) *Crowe et al* (1934) *Saxén* (1952) *Schuknecht* (1955) and *Ishii* (1967) failed to provide a sufficiently reliable explanation of the auditory lesions in patients with presbycousis consequently they postulated that degenerative lesions in old patients also might involve the more centrally localized areas This postulation was confirmed by *Kirikae et al* (1964) who in brains from 11 senile patients, found degeneration of ganglion cells in the ventral cochlear nucleus, in the superior olivary nucleus, in the inferior colliculus, and in the medial geniculate body

The present author has not been able to procure studies including detailed data concerning the correlation of the hearing capacity in man and the cortical processes, if any involving the auditory centres in the cerebral hemispheres.

Finally reports concerning the histopathologically demonstrable processes in the temporal bones and brains of senile patients with presbycousis are not available

patients Discrimination losses in five patients were in the range moderate to severe

Vestibular irrigation, using water at about 20–30 C, gave normal and uniform reactions in all patients

Four patients died of pulmonary diseases, two died of coronary sclerosis, one died after an apoplectic attack, and one died of metastases to the liver from a carcinoma of the gall bladder

Autopsy inspection of organs disclosed severe arteriosclerotic lesions in all cases.

The pathological findings in the temporal bones were of identical nature in all patients although the intensity of the degenerative lesions might vary individually (table 2)

The middle ear was of normal appearance in all but two patients, nos. 3 and 5 in whom the left ossicles were sites of severe osteitic lesions adherances through the middle ear were broad and the tympanic membrane had thickened.

In another patient, no 8 a cholesteatoma, not involving the ossicles, was in evidence, i e a "cholesteatoma *in situ*

All structures in the middle scale i.e the vascular stria, the sulcus cells, and the organ of Corti, were found to be deformed and flattened Changes varied from coil to coil from section to section and from the right to the left temporal bone in one and the same patient. Especially the appearance of the organ of Corti varied in most sections it was hardly recognizable, while structures appeared rather well preserved in other sections from the apical coil, the middle coil and the basal coil The tectorial membrane was displaced in relation to the organ of Corti while Reissner's membrane in many sections seemed to adhere downwards over the organ Lesions in the organ of Corti appeared to be uniformly dispersed throughout all coils

The basilar membrane had not thickened appreciably in any of the patients, particularly not at the site of the basal coil any calcareous deposits were not observed.

Vessels in the vascular stria and in the modiolus appeared to be normal in all

patients Discrimination losses in five patients were in the range moderate to severe

Vestibular irrigation, using water at about 20–30 C, gave normal and uniform reactions in all patients

Four patients died of pulmonary diseases, two died of coronary sclerosis, one died after an apoplectic attack, and one died of metastases to the liver from a carcinoma of the gall bladder

Autopsy inspection of organs disclosed severe arteriosclerotic lesions in all cases.

The pathological findings in the temporal bones were of identical nature in all patients although the intensity of the degenerative lesions might vary individually (table 2)

The middle ear was of normal appearance in all but two patients, nos 3 and 5 in whom the left ossicles were sites of severe osteitic lesions adherances through the middle ear were broad and the tympanic membrane had thickened

In another patient, no 8 a cholesteatoma not involving the ossicles was in evidence, i e. a "cholesteatoma *in situ*

All structures in the middle scale, i.e the vascular stria, the sulcus cells, and the organ of Corti were found to be deformed and flattened. Changes varied from coil to coil from section to section and from the right to the left temporal bone in one and the same patient. Especially the appearance of the organ of Corti varied in most sections it was hardly recognizable while structures appeared rather well preserved in other sections from the apical coil, the middle coil, and the basal coil The tectorial membrane was displaced in relation to the organ of Corti while Reissner's membrane in many sections seemed to adhere downwards over the organ Lesions in the organ of Corti appeared to be uniformly dispersed throughout all coils.

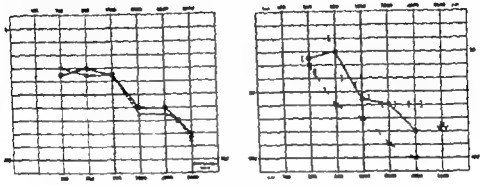
The basilar membrane had not thickened appreciably in any of the patients particularly not at the site of the basal coil any calcareous deposits were not observed

Vessels in the vascular stria and in the modiolus appeared to be normal in all

Additional sections of brains disclosed diffuse pathological processes similar to those observed in the auditory pathways.

Group II 2 patients

The past medical histories of the two patients concerned were similar to those of patients in group I and the audiometric findings in patients in the two groups were identical (cf fig 6, corresponding to figs. 24–25 in treatise B)



No 9 No. 10

Fig 6 Audiogram from the patients in group II. (nos 9–10, table 1).

In one patient (a 79-year-old man, cf. table 1) the impaired hearing may in part have been due to the noise produced by his trade since he throughout 56 years had been working as a cooper

One of these patients died of croupous pneumonia, the other of coronary thrombosis.

Findings obtained by histological examination of the middle ear the internal ear and the acoustic nerve were identical with the degenerative changes observed in patients in group I, table 2.

Both brains were sites of degenerative lesions like those seen in brains from patients in group I but atherosclerosis was not in evidence. The walls of arterioles had thickened, being of granular structure as otherwise seen in cases of senile atrophy

Thus, findings in the ten patients in groups I and II included, symmetrical loss of perceptive hearing, pathological processes involving the temporal bones, in particular the basal cochlear coil, and degeneration of the central auditory pathways and nuclei

Group III 1 patient

Group III comprises only one patient whose past medical history deviates from that of the aforementioned patients in that his loss of hearing had meant a handicap since he was about 38 years old. In addition, his blood pressure, systolic as well as diastolic, was elevated.

tory canal can be divided into two parts, one peripheral containing Schwann s cells and one central, glial part. In the peripheral part, disappearance and degeneration of myelin sheaths and axis cylinders would be of about the same order as in the basal coil of the spiral ganglion In the glial part, disappearance of myelin sheaths and axis cylinders was of about the same order while degeneration was by far more intense Numerous amyloid bodies were demonstrable at the junction between the two parts

It should be noted, however that Scarpa s vestibular ganglion as well as the vestibular nerve were sites of only few if any patho-anatomical lesions in all patients

At gross inspection of the central nervous system all brains were found to be diffusely atrophic infarctions were demonstrable in a few of the brains The leptomeninges were diffusely blurred.

Vessels in the circle of Willis were moderately to severely atherosclerotic Dilatation of the ventricular system was of varying degrees

Findings obtained by microscopy of the central auditory pathways included slight to moderate disappearance of cells in the glial part of the acoustic nerve and severe degenerative changes of myelin sheaths and axis cylinders The walls of intraneural vessels had thickened

Disappearance and degeneration of cells in the ventral and dorsal cochlear nuclei were symmetrical, being most marked in the latter Exactly the same type of lesions were demonstrable in the superior olivary nucleus, in the inferior colliculus, and in the med al geniculate body

Myelin sheaths and axis cylinders in the auditory pathways throughout the brain were swollen and unevenly calibrated

The white matter in the cortical auditory centres displayed varying degrees of thinning out with degeneration of myelin sheaths and axis cylinders

Focal and diffuse disappearance and degeneration of the cortical ganglion cells were in evidence in addition cortical malacias were manifest in three patients in one of these (no 1 in group I table 1) the left transverse gyri were involved in another (no 2 in group I table 1) both transverse gyri were involved, and in one patient (no 5 in group I table 1) the right transverse gyri were involved

Vessels in the cerebrum the brain stem and in the leptomeninges were severely damaged. In addition to the atherosclerotic lesions observed by gross inspection, the arteries and veins of intermediate size were sites of perivascular fibrosis the connective tissue in the walls had amplified The walls of arterioles were of a thickened homogenous appearance and the lumens were constricted, occasionally they might be totally occluded. Fibrillary thickening of the capillaries was in evidence

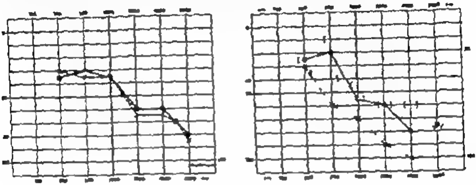
The pathological processes involving the cortex in the transverse gyri (the central auditory centres) were apparently not more severe than those in the auditory nuclei in the brain stem whereas processes involving the glial portion of the acoustic nerve and the white matter in the auditory centres were more severe than those in the auditory pathways through the brain stem

The processes seemed to occur symmetrically

Additional sections of brains disclosed diffuse pathological processes similar to those observed in the auditory pathways.

Group II 2 patients

The past medical histories of the two patients concerned were similar to those of patients in group I and the audiometric findings in patients in the two groups were identical (cf. fig. 6 corresponding to figs. 24–25 in treatise B)



No 9 No. 10

Fig. 6 Audiogram from the patients in group II. (nos 9–10 table 1)

In one patient (a 79-year-old man, cf. table 1), the impaired hearing may in part have been due to the noise produced by his trade since he throughout 56 years had been working as a cooper

One of these patients died of croupous pneumonia, the other of coronary thrombosis.

Findings obtained by histological examination of the middle ear the internal ear and the acoustic nerve were identical with the degenerative changes observed in patients in group I, table 2.

Both brains were sites of degenerative lesions like those seen in brains from patients in group I, but atherosclerosis was not in evidence. The walls of arterioles had thickened, being of granular structure as otherwise seen in cases of senile atrophy

Thus, findings in the ten patients in groups I and II included. symmetrical loss of perceptive hearing, pathological processes involving the temporal bones, in particular the basal cochlear coil, and degeneration of the central auditory pathways and nuclei.

Group III 1 patient

Group III comprises only one patient whose past medical history deviates from that of the aforementioned patients in that his loss of hearing had meant a handicap since he was about 58 years old. In addition, his blood pressure, systolic as well as diastole, was elevated.

3

The patient was a 60-year-old man who previously had been in good health his hearing had been normal During the last two years prior to death he became increasingly demented and complained of uncharacteristic vertigo and impaired hearing. One year before death, a haemorrhage in the right hemisphere occurred Audiometry revealed symmetrical loss of perceptive hearing the loss of hearing was of the presbycousis type and of a severity common in 75 year-old individuals, according to *Johansen*s findings in a series of normal subjects (*Johansen* 1943) cf fig. 7 corresponding to fig 26 in treatise B

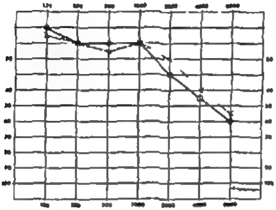


Fig 7 Audiogram from the patient in group III (no 11 table 1).

In addition, the loss of discrimination ranged at 67 %, determined by free-field speech audiometry

The patient died one year later in continuation of recurring cerebral vascular episodes.

It should be emphasized that the brain was fixed *in situ* about 10 minutes after death had occurred.

Autopsy inspection of organs revealed severe generalized atherosclerosis.

Microscopy of the temporal bones (table 2) The organ of Corti was of normal appearance. The walls of the cochlear vessels were slightly thickened The cochlear spiral ganglion was normal

Axis cylinders in the peripheral part of the acoustic nerve had not disappeared but sporadic demyelination was in evidence intensifying towards the glial part.

Vessels in the internal auditory canal and the acoustic nerves were markedly arteriosclerotic

All lesions of the temporal bones were symmetrical.

At gross inspection and by microscopy of the brain, the right hemisphere was found to be a site of a massive fresh haemorrhage and atrocious atherosclerosis In the glial part of the acoustic nerve, demyelination was sporadic intensifying towards the cerebrum where it was almost generalized. The preserved structures in the auditory pathways and centres were sites of histologically demonstrable lesions similar to those observed in patients in group I

Group IV 1 patient

Also group IV comprises only one patient in whom findings deviated from those observed in patients in the other groups in that audition in the left ear was extinct. Furthermore, the patient was a chronic alcoholist.

The patient was a 69 year-old man. As far as he was able to remember hearing with his left ear had always been poor although he did not know why Since childhood, hearing with his right ear had been fluctuating on account of periodic episodes of otitis media.

Audiometry performed six years prior to his death had disclosed that audition in his left ear was extinct, audition in the right ear could not be reliably determined (cf fig. 8 corresponding to fig. 29 in treatise B) The patient being very shy it proved impossible to decide whether the right-sided loss of hearing was of the sound-conduction type or of the perception type. Also speech audiometry proved a failure

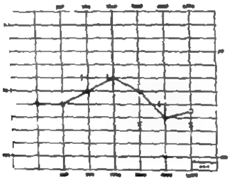

Fig. 8 Audiogram from the patient in group IV (no. 12, table 1)

The patient died when he was 69 years old, the cause of death being postoperative complications after prostatectomy

Autopsy inspection of organs disclosed acute pyelonephritis. Arteriosclerotic changes, if any were very mild

By microscopy of the right temporal bone, the middle ear and the mastoid process were found to be sites of chronic, inflammatory lesions. The ossicular chain and the tympanic membrane were intact and adherences in the middle ear were only few Otherwise findings were similar to those observed in patients in groups I and II

Examination of the left temporal bone displayed normal conditions in the middle ear Nothing of the organ of Corti remained well-preserved. Labyrinthine hydrops, involving also the saccule, was manifest. Cells in the spiral ganglion had disappeared almost completely and myelin sheaths and axis cylinders were scarce in the acoustic nerve.

After fixation of the brain it weighed 1300 gram It appeared normal to the gross view and without signs of arteriosclerosis.

Microscopy of the brain disclosed disappearance and degeneration of axis cylinders and myelin sheaths in the glial part of the acoustic nerve On the right side the changes were moderate, disappearance of cells being almost total on the left side where also the few remaining axons had degenerated.

The auditory nuclei throughout the brain stem were sites of moderate degenerative changes and the cerebral cortex displayed mild atrophy

The most severe pathological lesions were localized to the white matter in the brain stem as well as to auditory centers in the cerebral hemispheres where disappearance of cells was marked and degeneration of myelin sheaths severe similar lesions were demonstrable also in areas other than the auditory pathways.

The most significant findings clinical as well as histological in this patient included audition in the left ear was extinct, audition in the right ear being severely impaired almost total disappearance of neurones in the left spiral ganglion, and moderate degree of disappearance and degeneration of neurones in the right spiral ganglion of the cochlea. The brain was a site of diffuse demyelinization

Discussion

A brief account is given concerning data included in the past medical histories of the 12 patients comprised in this series together with descriptions of the severity of their loss of hearing and the pathological processes observed in their temporal bones and brains

The question to arise is whether it may be possible on the basis of the obtained findings to single out such lesions of peripheral and/or central elements in the auditory pathways as may be responsible for the loss of hearing.

The most essential pathological findings in temporal bones of patients in groups I and II included

Flattening of the organ of Corti which, in most cases, may have occurred after death. Uniform rather moderate vascular changes throughout the cochlea. Slight to moderate disappearance of cells in the basal coil of the spiral ganglion together with degenerative lesions involving the peripheral part of the acoustic nerve, paralleling the changes of ganglion cells. All of the observed findings were symmetrical

The pathological processes in the central auditory pathways were also symmetrical The slight to moderate disappearance of nerve fibres and the severe degeneration of the central glial part of the acoustic nerve were more marked than the disappearance and degeneration in the peripheral Schwann part degeneration of auditory pathways through the brain stem of the cortex was obviously most marked in the white matter of the cerebral hemispheres. Furthermore, atrophy of the cerebral cortex was manifest, being particularly marked in the two patients belonging in group II

Flattening of the organ of Corti and of other structures in the middle scale was observed in 11 patients. According to previous publications, this feature need not be a constant finding in elderly patients with poor hearing the phenomenon has been observed also in subjects whose hearing was normal (Crowe et al

1934 *Saxén* 1952) Furthermore, the epithelial lesions may have occurred after the death of the patients and thus, they cannot have been responsible for their loss of hearing (*Lange* 1937 *Fleischer* 1956) The latter is corroborated by the fact that the organ of Corti was found to be normal in the patient belonging to group III as well as in the 43-year-old male patient with fluctuating audition in whom a glioblastoma developed the patient has been discussed in chapter II. In both cases, the organs were fixed within 10 minutes after death.

Loss of perception of tones in the low-frequency range varied in these patients although the ganglion cells in the apical and middle coils seemed to be normal, or only slightly degenerated, thereby excluding that this part of the hearing loss was due to cochlear changes. The same conclusion has been drawn by *Saxén* (1952) on the basis of findings in his series.

The basal coil was the site of slight to moderate disappearance of ganglion cells to a certain extent, although not completely this feature may explain why the hearing of high tones was impaired in these patients. The lesions concerned, however were not more severe than those which according to the available literature may be encountered in patients with normal hearing (*Crowe et al.* 1934 *Schuknecht* 1955 *Citron et al.*, 1963)

If the rather slight vascular changes in the cochlea actually had exerted an influence on the organ of Corti and on the degenerative processes in ganglion cells, degeneration might be expected to be uniform throughout all coils because the vessels were of uniform appearance throughout the cochlea.

To all appearances, the degenerative changes of the peripheral (Schwann) part of the acoustic nerve seemed to equal those of the ganglion cells pertaining to the basal coil These changes seemed out of proportion to the very severe changes involving the extraneural vessels within the internal auditory canal.

By way of comparison it should be noted that the vestibular nerve as well as Scarpa's ganglion were normal degeneration, if any was of a mild degree in all patients

In the central auditory pathways, degeneration was of a severe character in the glial part of the acoustic nerve and in the white matter in the brain stem as well as in the auditory centres in the cerebral hemispheres. The changes were more pronounced in the cerebral hemispheres than in the white matter of the brain stem

The pathological processes in the auditory nuclei in the cortex were a little less pronounced than those involving the axons and axis cylinders in the auditory pathways

The cerebral changes might be due either to advanced age or to impaired vascular conditions It must be admitted, however that the cortical atrophy diagnosed in patients in group II was appreciable

There is reason to believe that the above discussed pathological processes involving the central nervous system in patients in groups I and II may have compromised their audition hence, lesions involving the cerebral sections of the auditory pathway may have been responsible for the loss of hearing, in particular that applying to low tones, to a minor degree that applying to high tones.

It is rather remarkable that the cochlear structures were normal throughout in

Microscopy of the brain disclosed disappearance and degeneration of axis cylinders and myelin sheaths in the glial part of the acoustic nerve. On the right side, the changes were moderate, disappearance of cells being almost total on the left side where also the few remaining axons had degenerated.

The auditory nuclei throughout the brain stem were sites of moderate degenerative changes and the cerebral cortex displayed mild atrophy

The most severe pathological lesions were localized to the white matter in the brain stem as well as to auditory centers in the cerebral hemispheres where disappearance of cells was marked and degeneration of myelin sheaths severe similar lesions were demonstrable also in areas other than the auditory pathways.

The most significant findings clinical as well as histological in this patient included audition in the left ear was extinct, audition in the right ear being severely impaired almost total disappearance of neurones in the left spiral ganglion and moderate degree of disappearance and degeneration of neurones in the right spiral ganglion of the cochlea The brain was a site of diffuse demyelinization

Discussion

A brief account is given concerning data included in the past medical histories of the 12 patients comprised in this series together with descriptions of the severity of their loss of hearing and the pathological processes observed in their temporal bones and brains

The question to arise is whether it may be possible on the basis of the obtained findings to single out such lesions of peripheral and/or central elements in the auditory pathways as may be responsible for the loss of hearing.

The most essential pathological findings in temporal bones of patients in groups I and II included

Flattening of the organ of Corti which, in most cases, may have occurred after death Uniform, rather moderate vascular changes throughout the cochlea Slight to moderate disappearance of cells in the basal coil of the spiral ganglion together with degenerative lesions involving the peripheral part of the acoustic nerve paralleling the changes of ganglion cells All of the observed findings were symmetrical

The pathological processes in the central auditory pathways were also symmetrical The slight to moderate disappearance of nerve fibres and the severe degeneration of the central glial part of the acoustic nerve were more marked than the disappearance and degeneration in the peripheral Schwann part degeneration of auditory pathways through the brain stem of the cortex was obviously most marked in the white matter of the cerebral hemispheres. Furthermore atrophy of the cerebral cortex was manifest, being particularly marked in the two patients belonging in group II

Flattening of the organ of Corti and of other structures in the middle scale was observed in 11 patients According to previous publications this feature need not be a constant finding in elderly patients with poor hearing the phenomenon has been observed also in subjects whose hearing was normal (*Crowe et al*

In fact, it was not possible in any of the 12 patients concerned to demonstrate a correlation between the degree of the pathological processes in the internal ear and the demonstrable loss of hearing, no matter whether the hearing loss applied to tones in the high- or low-frequency range.

The conclusion to be drawn is therefore that loss of hearing "pertaining to age" presenile loss of hearing of the presbycousis type, as well as loss of hearing displaying audiometric curves of different configurations, apparently occur as sequelae of pathological processes involving the cerebrum as well as the temporal bones.

the patient in group III while sporadic demyelinization intensifying towards the cerebrum where it was almost generalized was in evidence in the acoustic nerve In this case it proved rather difficult to inspect the white matter and the cerebral cortex because of the oedematous nature of these From a clinical point of view however the patient concerned was almost completely demented and hence, the pathological processes to precede the acute and fatal attack must have been of a severe degree

This patient's loss of hearing applied almost exclusively to tones in the high-frequence range and, as the cochlea was of normal appearance the hearing loss could hardly be attributable to cochlear factors It may rather have been due to changes in the acoustic nerve and in the central nervous system

Lesions involving the right cochlea and the acoustic nerve in the patient in group IV were identical with those encountered in patients in groups I and II It should be mentioned, however that mild chronic, inflammatory changes involving the middle ear on the right side were manifest in the former patient. The degree of the inflammatory lesions was not more severe than that otherwise seen in patients with normal hearing (Crowe et al 1934)

The auditory pathways in the brain stem and in the cerebral hemispheres were sites of symmetrical extremely severe pathological processes in the white matter processes were less pronounced in the nuclei and the cortex, Arteriosclerosis was not in evidence It seems reasonable to conclude on the basis of these findings that the right-sided loss of hearing was due mainly to cerebral changes in this patient.

Flattening of the organ of Corti in the left ear where audition had been extinct throughout years, was more marked than that in the right ear hydrops was manifest and the spiral ganglion as well as the acoustic nerve were almost completely eliminated Since lesions in the central nervous system were symmetrical it seems reasonable to presume that the left-sided loss of hearing, in excess of the right sided loss might be ascribable to the degenerative processes in the peripheral organ

On the basis of the findings in these 12 patients it seems justified to conclude that pathological cochlear lesions were not solely responsible for their loss of hearing, rather the pathological processes in the brain may have played some role probably even a major role

Hearing losses observed in these 12 patients were in some cases of the presbycousis type but hearing curves of other configurations were also obtained.

For instance the hearing loss experienced by the 60-year-old patient (no 11 group III) was of the presenile type and the hearing curve obtained in that case reminded of the one seen in cases of presbycousis which, according to the available reports may be encountered in 75 year-old subjects whose audition is per taining to age"

Furthermore the loss of hearing of tones in the high frequency range in patients nos. 6 and 7 in group I was more marked than that otherwise seen in patients whose hearing is impaired because of age In four patients (nos. 1 3 and 4 in group I and no 1 in group IV) the loss of hearing applying to the low frequency range was also of a more severe degree than otherwise seen among patients whose hearing is impaired because of age

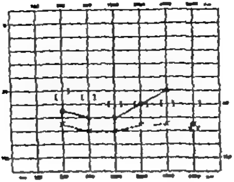

Fig. 9. Hearing curve from the senile patient with Ménière's disease.

throat, but the origin of this complaint could not be defined an inexplicable paralysis of the right vocal cord was diagnosed.

The patient died at the age of 83 years.

Autopsy inspection of organs disclosed "Thrombosis a. pulm sin. et infarctus lobi inf. pulm sin. pneumonia sin. and atrophia fusca et arteriosclerosis organorum in gr."

Microscopy of the right and left temporal bones

The cochleae were sites of bilateral labyrinthine hydrops, most severe on the right side where also the sacculus was involved. The right utriculus was slightly dilated while the semicircular canals appeared to be normal. The tectorial membrane was apparently forced downwards over the organ of Corti. Some areas of Reissner's membrane were of atrophic appearance while proliferation of epithelial cells was in evidence in other areas.

In the right spiral ganglion of the cochlea, the disappearance of cells was of a rather considerable degree at the level of the basal coil, being almost negligible at levels of the middle and apical coils. An even higher degree of disappearance of cells was observed in the left spiral ganglion where it was most pronounced at the level of the basal coil.

In the peripheral part of the right and left acoustic nerves the disappearance of axons was appreciable, being almost of the same order as the disappearance of ganglion cells remaining axons had degenerated, most markedly on the left side.

The vestibular portions of the labyrinth were of normal appearance on either side which also applied to Scarpa's vestibular ganglion and the vestibular nerve.

Gross inspection of the cerebrum.

(1) A subdural haematoma of long standing was in evidence over the anterior portion of the right cerebral hemisphere.
(2) Diffuse cortical atrophy.
(3) Moderate blurring of the leptomeninges.
(4) Atherosclerotic lesions involving the circle of Willis and extending into the peripheral ramifications.

CHAPTER V

Pathological Processes Involving the Temporal Bone and the Cerebrum in a Senile Patient with Ménière's Disease

The present chapter comprises a review of the past medical history of an 83-year old patient with Ménière's disease together with a summary of the histological findings in the temporal bones and the brain of this patient. The clinical and histological findings are collated with those obtained in similar studies of Ménière's disease as reported in the relevant literature A more detailed account is available in treatise C

The patient was an 83 year-old woman who always had enjoyed a good health, apart from chronic arthritis and moderate dyspeptic complaints

At the age of 50 years, the patient had been hospitalized on account of Ménière's disease manifesting itself as intensifying tinnitus, impaired right-sided hearing capacity and episodes of vertigo She managed to hear speech whispered *ad aurem* and hearing with the left ear remained normal

Episodes of vertigo subsided but her sensations of instability as well as the right sided tinnitus and the ipsilaterally reduced hearing persisted

Ten years later the episodes of vertigo recurred (any detailed data are not available) Hearing with the left ear remained uncharged and satisfactory

At the age of 77 years, i e 27 years after onset of the initial symptoms episodes of vertigo recurred frequently and hospitalization was required. Moreover hearing with her left ear failed and all sounds seemed to be distorted. Audition tests at that time revealed. whispers r/l = aa (ad aurem)/ 0.50 meter speaking voice r/l = aa/3–4 meter

Vestibular irrigation disclosed a severely reduced caloric functioning of both ears Romberg's test was positive when the patient was walking with her eyes closed, she would constantly be deviating to the left. Episodes of vertigo subsided within a couple of weeks A cataleptic attack occurred while she was in hospital.

At the age of 78 years the patient applied for treatment in the State Hearing Centre in Aarhus furthermore, she wanted to have a hearing aid. Audiometry disclosed a severe bilateral deafness of the perception type, cf fig. 9 corresponding to fig. 1 in treatise C.

Speech audiometry revealed that the left-sided threshold of intelligibility ranged at 50 db the loss of discrimination ranging at 90 %. The patient managed to perceive sounds, but not speech with her right ear She complained of non-gyratory vertigo and besides a high pitched tone persisted in both ears. She was supplied with a hearing aid but she had no benefit from it and returned it

At the age of 79 years the patient consulted an otologist because of a sore

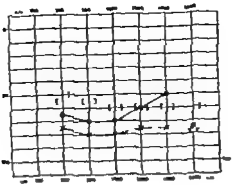

Fig. 9 Hearing curve from the senile patient with Ménière's disease.

throat, but the origin of this complaint could not be defined an inexplicable paralysis of the right vocal cord was diagnosed.

The patient died at the age of 83 years.

Autopsy inspection of organs disclosed. "Thrombosis a. pulm sin. et infarctus lobi inf. pulm sin pneumonia sin, and atrophia fusca et arteriosclerosis organorum in gr

Microscopy of the right and left temporal bones.

The cochleae were sites of bilateral labyrinthine hydrops, most severe on the right side where also the sacculus was involved. The right utriculus was slightly dilated while the semicircular canals appeared to be normal. The tectorial membrane was apparently forced downwards over the organ of Corti. Some areas of Reissner's membrane were of atrophic appearance while proliferation of epithelial cells was in evidence in other areas.

In the right spiral ganglion of the cochlea, the disappearance of cells was of a rather considerable degree at the level of the basal coil, being almost negligible at levels of the middle and apical coils An even higher degree of disappearance of cells was observed in the left spiral ganglion where it was most pronounced at the level of the basal coil.

In the peripheral part of the right and left acoustic nerves the disappearance of axons was appreciable, being almost of the same order as the disappearance of ganglion cells remaining axons had degenerated, most markedly on the left side

The vestibular portions of the labyrinth were of normal appearance on either side which also applied to Scarpa's vestibular ganglion and the vestibular nerve.

Gross inspection of the cerebrum.

(1) A subdural haematoma of long standing was in evidence over the anterior portion of the right cerebral hemisphere.
(2) Diffuse cortical atrophy
(3) Moderate blurring of the leptomeninges.
(4) Atherosclerotic lesions involving the circle of Willis and extending into the peripheral ramifications

Microscopy of the central auditory pathways.

Severe degrees of disappearance and degeneration of axons in both acoustic nerves, but most pronounced in the left. The auditory pathways and nuclei were sites of severe outfall and degeneration of ganglion cells and axons Ganglion cells in both auditory centres had also disappeared and degenerated the disappearance and degeneration of myelin sheaths and axis cylinders in the white matter were of a similar severe degree

Microscopy of the central vestibular pathways and centres.

The glial part of the vestibular nerves on both sides had degenerated The course of nerves between the restiform body and the nucleus of the spinal tract of the trigeminal nerve could not be reliably followed The lateral medial and superior vestibular nuclei on either side displayed excessive disappearance and severe degeneration of ganglion cells, the phenomenon being most marked on the left side

Furthermore, severe diffuse degeneration of nuclei and pathways throughout the brain stem was demonstrable in this patient lesions seemed to be most pronounced in the vestibular parts of the nuclei of the cranial nerves

Vessels in the brain stem and the cerebrum displayed signs of capillary fibrosis, arteriolosclerosis, and atherosclerosis.

Thus, in this 83 year-old patient who since the age of 50 years had been suffering from Ménière s disease and in whom an additional loss of hearing of high tones had been ascertained when she was 77 years old findings included

(1) Bilateral labyrinthine hydrops
(2) Degeneration and disappearance of neural elements in the acoustic nerves, parallel to features in the corresponding spiral ganglion of the cochlea and most pronounced on the left side
(3) A normal left Scarpa s ganglion (the one on the right side was not included in the sections) and a rather mild degree of degeneration of axons in the Schwann part of both vestibular nerves
(4) Disappearance and severe degeneration of structures in auditory as well as vestibular central nuclei and pathways

Discussion

The clinical and histopathological findings in this patient shall be briefly discussed and be related to findings obtained in previous works by other investigators

A Lesions involving the epithelial portion of the labyrinth

(1) *Labyrinthine hydrops*

Mygind & Dederding (1938) were the first who recognized that changes in the endolymphatic pressure might be responsible for various degrees of hearing loss applying to the low frequency range when episodes of Ménière s disease occurred

this hypothesis has later been corroborated by experiments on models as well as in animals (*Tonndorf* 1957 *McCabe & Wolsk*, 1961) *Arslan et al.* (1963) arranged sodium chloride crystals on the round window in man, thereby changing the pressure in the labyrinth this procedure would be followed by a development of typical attacks of Ménière's disease in the patient concerned.

On the assumption that the intralabyrinthine hydrops was the exclusive cause of the patient's loss of hearing, audition should be expected to be reduced to a degree paralleling the degree of distension of Reissner's membrane. In the case at issue however audition was best preserved in the right ear in which hydrops was most severe and most widespread. Furthermore hydrops was unilateral and involved the sacculus in one senile patient (no 7 in group I) discussed in chapter IV this patient did not present symptoms of Ménière's disease whereas his loss of perceptive hearing, confined to the high-frequency range, was symmetrical. Also the loss of discrimination was equal on both sides. This invalidates the theory that hydrops per se was solely responsible for the hearing loss applying to the low-frequency range

Descriptions of labyrinthine hydrops associated with dilatation of the sacculus are on record (*Rollin* 1940; *Kristensen* 1961) In the patient here concerned, dilatation of the sacculus was of an unilateral nature while hydrops in the cochlear coils was bilateral.

(2) *Injury to the organ of Corti*

Pathological lesions of the organ of Corti as well as their importance for audition are not easy to evaluate *Schuknecht* (1953) and *Kristensen* (1961) observed in their patients with severe hydrops that the pathological processes were most pronounced in the apical coil and thus, might account for the hearing loss applying to low tones On the other hand, *Lindsay & Schuknecht* (1958) found that the organ of Corti seemed to be fairly normal at the site of the apical coil whereas the loss of ganglion cells in the same area was rather appreciable In patients with Ménière's disease however there will always be some recruitment which serves to confirm that the function of hair cells is reduced (*Dix et al* 1948 *Hood* 1961)

In the present case it could not be reliably ascertained whether the changes in the organ of Corti were more severe than those otherwise seen in cases of presbycusis in patients of equivalent ages (chapter IV) on the contrary sections from all coils gave evidence of a surprisingly well-preserved organ of Corti.

(3) *Changes involving the remaining epithelial structures in the middle scale*

According to available reports, specific changes of supporting cells in the cochlea, the vascular stria, the basilar membrane, and the tectorial membrane, have not been observed in patients with Ménière's disease and were not seen either in the present case

(4) *Changes involving the epithelial portion of the peripheral vestibular organ*

Endolymphatic hydrops in the semicircular canals has never been observed in patients with Ménière's disease and the utriculus is rarely involved (*Hallpike &*

Cairns 1938 *Rollin* 1940 *Lindsay* 1960 *Kristensen* 1961 1962) Electron microscopy revealed lesions involving the superficial layers of the sensorial ephithelium in the ampullae of the semicircular canals (*Pietrantoni & Iurato* 1960 *Litton & Lawrence* 1961) The latter authors held that the pathological changes had been in evidence prior to death and also that the process responsible for the development of Ménière s disease might bring about a cytotoxity that was seen to persist almost until cell death accordingly the peripheral vestibular function would be reduced, it might even be discontinued

It seems rather difficult, however to explain the intensive vestibular symptoms solely as sequelae of the pathological processes in the labyrinth *Busanny-Caspari & Matzker* (1960) did not observe any signs of hydrops in a lateral semicircular canal which was removed at the moment when the patient had a severe attack of Ménière s disease Moreover *Lindsay* (1960) found vestibular reactions to be normal in patients with highly advanced hydrops Even so *Lindsay* postulated that the vestibular reactions to occur during attacks are best explained on the assumption of an existence of a factor of mechanical nature which may upset the ampullary mechanism in one or more ampullae

Apart from the moderate dilatation of the right utriculus, pathological processes in the vestibular portion of the labyrinth were not in evidence in the patient here discussed

B Changes involving the neural elements of the labyrinth

(1) *The auditory portion of the labyrinth (1st neurone of the auditory pathways)*

Several authors have observed in patients with Ménière s disease that the pathological processes in ganglion cells in the apical cochlear coil paralleled the loss of hearing of tones in the low frequency range (*Rollin* 1940 *Lindsay & Schulthess* 1958 *Lindsay* 1960 *Kristensen* 1961) Such hearing loss has been produced in cats via lesions induced to the apical cochlear coil (*Schuknecht & Neff* 1952)

In the patient at issue ganglion cells in all cochlear coils were found to be damaged mainly those in coils of the left cochlea the latter is commensurate with the fact that her hearing on the left ear was most severely impaired In contrast, in the senile patients discussed in chapter IV (groups I II and III) the hearing impairment as well as the pathological processes were symmetrical

Disappearance and degeneration of neural elements were also found to be most intense in the peripheral part of the left cochlear nerve where it paralleled the degree of disappearance of ganglion cells in the spiral ganglion of the cochlea.

Dandy (1937) observed usually a large arterial branch in touch with the cochlear nerve in patients with Ménière s disease This phenomenon was not observed in our patient

(2) *The vestibular portion of the labyrinth (1st neurone of the vestibular pathways)*

The incongruity between the, often severely reduced caloric vestibular reaction and the histological findings in the vestibular portion of normal labyrinths represents

an outstanding phenomenon which has been observed previously by other investigators (e g. *Kristensen* 1961) as well as by the present author

C Changes involving the cerebral cochlear and vestibular neurones

(1) *The auditory pathways and centres*

A review of the relevant literature as well as the clinical data obtained (chapter IV) suggest that a loss of hearing of tones in the low frequency range may represent the sequelae of lesions involving sites centrally to the cochlea, either in the auditory nerve or in the brain stem. *Lundborg* (1955) *Gravendeel* (1958), *Gravendeel & Plomp* (1960), and *Parker et al* (1962) have advanced the same hypothesis.

In the patient here discussed, changes of the ganglion cells in the 1st neurone were not sufficiently marked to represent the factor exclusively responsible for the loss of hearing, whether of tones in the low- or high-frequency range accordingly such hearing loss must be attributable to factors localized to central sites considering the histological findings in the central auditory pathways, the latter seems most probable

(2) *The vestibular pathways and centres*

Reports concerning histological studies of the cerebral vestibular neurones in patients with Ménière's disease are not available. Electronystagmographic curves obtained in cases of this disease have revealed, however some features suggestive of cerebral lesions (*Aschan & Stahle* 1957 *Montandon* 1959 *Maspétiol et al.* 1961) This finding has been corroborated by *Rossberg* (1960) and *Maspétiol et al.* (1962) who for instance, on the basis of clinical deliberations suggested that the vegetative and nystagmogenic centres in diencephalon might be affected in patients with Ménière's disease Stimulation of the hypothalamus in cats has been found to change the rate of velocity of blood perfusion in the cochlea (*Morizono* 1966). Thus inspired, it might be worthwhile to consider whether irritative disorders in the central nervous system might exert an influence on the pressure in the internal ear

In the patient here concerned, the extremely severe lesions involving the central vestibular nuclei and pathways were by far more intense than those in the other structures of the brain stem the latter is in contrast to the fact that the peripheral neurones remained well-preserved.

(3) *Additional cerebral lesions*

Several authors have observed neurological symptoms other than those pertaining to Ménière's disease, indicating a presence of cerebral lesions. According to *Crowe* (1937) the patients might become unconscious, diplopia of transient nature might occur and occasionally the corneal sensitivity on the same side as the audio-vestibular symptoms might be reduced. *Podvinec et al.* (1961) observed paralysis of the trigeminal nerve associated with endolymphatic hydrops, in 9 out of 18 patients in one patient, Bell's paresis was seen to develop coincidentally

with the primary episode of Ménière s disease *Greiner et al* (1954) saw one patient in whom the lesion developed along with syringomyelia

The patient here concerned had cataleptic attacks, unilateral paresis of the vocal cord, positive Romberg s symptom, and besides, she would constantly be deviating to the left if she were walking with her eyes closed symptoms which all may be attributable to diffuse cerebral lesions

Furthermore some authors have suggested that the aetiology of Ménière s disease might include cerebral vascular lesions and accordingly that "vascular crises" might be responsible for the sporadically occurring symptoms For instance, symptoms of Ménière s disease have repeatedly been observed in patients whose complaints might be ascribable to vascular diseases such as Quincke s oedema (*Dederding* 1929) glaucoma (*Godtfredsen* 1949 *Hilger* 1950) migraine (*Sørensen* 1959) lesions of the conjunctival vessels (*Naito* 1962) and extensive vascular disorders exciting symptoms of transient nature in the trigeminal nerve and the facial nerve" (*Podvinec et al* 1961)

In the present case, the vascular changes were never seen to be of a degree more severe than that otherwise seen in senile patients like the ones discussed in chapter IV especially not the lesions at the site of the circle of Willis.

It emerged from the review of the literature that opinions of and views on the localization or localizations, of the pathological processes responsible for a development of Ménière s disease were highly conflicting

On the basis of the histological findings in the patient here concerned it may be presumed that her symptoms were due to lesions at peripheral as well as central sites, mainly to those at central sites Whether the patient s loss of hearing of high tones is to be taken as a symptom of Ménière s disease or it was due rather to her age and the severe arteriosclerosis, remains to be decided, but the pathological findings suggest that her hearing loss applying to the high-frequency range originated in lesions at peripheral and especially at central sites

PART 2

Studies of Vessels in Temporal Bones after Injection of Contrast Medium

The subject matter of Part 2 is the results obtained by injection of contrast medium into vessels of human temporal bones. The primary object was to investigate whether vessels in the membraneous labyrinth have to pass a capillary system before they come into communication with vessels in the surrounding osseous structures. Another object was to describe the anatomy of the vascular pattern in the cochlea and the acoustic nerve in subjects at various ages, in an attempt to defining the aetiology of the lesions discussed in Part 1

Chapters VI VII VIII and IX are abstracts of the previously published treatises D E, F and G chapter X contains a summary of all findings obtained and discussed in parts 1 and 2 and the ensuing conclusions

CHAPTER VI

Material and Methods

The material comprises 43 temporal bones from a total of 33 individuals at ages ranging between five days and 94 years.

Any selection of specimens has not been possible the material comprises 11 temporal bones from 11 "unclaimed bodies" autopsied in the Los Angeles County Hospital, together with 32 temporal bones from 23 patients who died in Odense Amts og Bys Sygehus (the University Hospital in Odense)

The group termed unclaimed bodies" comprises the bodies of patients who died in the Los Angeles County Hospital or had been brought into the hospital with a view to post-mortem examination and subsequent embalming. The clinical findings were not specified. According to a rough estimate based on data provided by the pathologist, ages of these subjects ranged above 50 years the sex of patients is not on record The author removed the first specimens, but received later temporal bones that had been removed by members of the staff trained for this purpose.

After moving to Odense, the author removed specimens from patients there. Temporal bones were obtained from 7 women and 15 men. The ages of patients were as follows One 5-day-old boy (premature by two months) the age group 20–29 years included one man the age group 40–49 years included two women and one man the age group 50–59 years two women and three men, the age group 60–69 years one man the age group 70–79 years, two women and four men the age group 80–89 years one woman and two men, finally two men were 92 and 94 years old, respectively Audiological and otological examinations had been performed in three of these cases reduced hearing of the presbyacusis type was diagnosed in all three

The patients died of diseases which had not affected the temporal bones *except* in cases where the pathological changes were sequelae of generalized arteriosclerosis

As regards patients who died in the Odense hospital, the bodies were transferred to the morgue about 6 hours after death and kept there at about -5 C. The patients who died in Los Angeles were also kept in the morgue, but intervals between death and transfer to the morgue might be of varying lengths.

The temporal bones were removed as soon as possible after death in the case of bones obtained from patients in Los Angeles, they were removed about 24–48 hours after death, but prior to embalming. Temporal bones from patients who died in the Odense Hospital were removed at intervals after death ranging between 7 [illegible]

The temporal bones were removed and prepared in accordance with the follow ing method elaborated by the author (cf. treatise D)

1 The cerebral hemispheres were tilted backwards The tentorium cerebelli was cut as close as possible to the superior petrosal sinus The cranical nerves I–VI and the internal carotid arteries were bisected, upon which the cerebral hemispheres could be everted further backwards
2. Prior to further dissection the anatomy of vessels and nerves in the cerebello-pontine region was studied As to the series originating in Odense a substance with a particle size of 0 1 micron in 1 % aqueous solution (Lichtblau 2 R 'Bayer'') was injected in order to facilitate identification of vessels and, if possible, to make photographic studies The results obtained in these experiments (unpublished data) were submitted in a lecture read to the "Inter national Course in Transtemporal Microsurgery of the Internal Auditory Canal" Zürich, March 1970
3 The glial part of nerves VII and VIII was cut at the site of their entrance into the brain stem Furthermore, about 3–4 cm from the medial orifice of the internal auditory canal and the subarcuate fossa, the vascular system which enters into the temporal bone from the posterior surface of the petrosal part was cut off In order to have a sufficiently large vascular section available for the later injections part of the cerebellum was usually included. The mass of tissue thus produced was cautiously covered by gauze which served as protection during removal of the temporal bones
4 Care was taken to spare the temporal bone squama while the petrosal part, portions of the mastoid process the middle ear and the medial portion of the external auditory canal were removed The damage thus inflicted to the base of the skull was trifling and both temporal bones could be excised
5 The specimens were immersed in physiological saline and taken to the laboratory where they either immediately or after storage in the refrigerator at about —4 C for some days were kept in a specific holder designed by the author and built by Jack Urban, Urban Engineering Co Burbank, California. It is an advantage of this holder that it permits dissection from all angles (cf fig 2, treatise D) moreover fitting of a small platform makes it possible to keep the aforementioned mass of vessels and nerves level with the medial orifice of the internal auditory canal. Fitting of another specially designed equipment for vascular injections permitted delicate manipulation and sufficient stability
6 A surgical microscope was used while a syringe was inserted into the vessel or vessels into which injections were applied. All other vessels were com pressed by micro-bulldog clamps Subsequently the injections could be applied without wasting much of the contrast medium

According to the experience gained by the author the time interval between death and removal of temporal bones as well as the interval between removal of bones and injection of contrast medium, were of no significance for the results to be obtained

Vessels were traced in accordance with the following techniques.

a. Injection of "Microphil" (Canton-Bio-Medical Products, Canton, Mass.)
b. Injection of suspensions of various porcelain dyes, namely sulphides containing circular grains of sizes ranging between 0.5 and 1 micron in 10 / gelatine. The suspensions were prepared by the author.
c. Histochemical demonstration of the alkaline phosphatases of vascular walls, thereby reproducing the vessels in a distinct, reddish-violet contrasting colour. Initially the enzyme in the vascular walls had been fixed by injection throughout 30 *minutes* into the specimen, using buffered (pH about 7) formalin calcium (1 % $CaCl_2$ in 4 % formaldehyde) at room temperature, immediately followed by continued injection throughout 30 minutes of about 10 ml of Burstone's azo-solution for the staining of alkaline phosphatases.

The solution was prepared as follows:

(a) Naphthol As-Bi *phosphoric* acid (Sigma Chemical Company) 4–5 mg dissolved in 0.25 ml of N N-dimethyl formamide
(b) addition of 5 ml of distilled water
(c) addition of 5 ml of 0.2 mol Tris buffer (pH 8.3–9.0)
(d) addition of 30 mg of Red Violet LB in the form of diazonium salt followed by vigorous shaking of the mixture
(e) the incubation medium was filtered and immediately injected into the specimen

The result appeared in the form of a reaction product of a reddish-violet colour.

Since the reddish-violet colour might be rather close to the bluish violet colour which at the subsequent microscopy of the specimens was seen to develop as an optic error, a solution comprising exclusively formol calcium, but no subsequent injection of azo-dye, was injected into one control specimen (not included among the above mentioned 43 specimens).

All of these solutions (a, b, and c) were preferably injected under physiological pressure, oscillating between systolic and diastolic rates of pressure. Injections into temporal bones from unclaimed bodies were applied at pressures ranging around 150 mm mercury owing to the lack of data concerning these patients.

In the case of solutions of type "a" processes of injection covered 15 minutes, covering 30 minutes in the cases of types "b" and "c".

In some temporal bones differently coloured contrast media were injected into various vessels in order to demonstrate vascular anastomoses, if any, between the individual vascular systems into which injections had been applied. In order to demonstrate whether anastomoses between the basilar artery and branches of the carotid artery were in evidence, a dye material was injected into seven temporal bones via branches of each of the two arterial systems. Injection into branches of the carotid system was *performed in the* autopsy room after the common carotid artery had been clamped at the site inferior to the site of injection; the internal carotid artery was clamped at an intracranial site close to the cavernous

The temporal bones were removed and prepared in accordance with the following method elaborated by the author (cf. treatise D)

1 The cerebral hemispheres were tilted backwards. The tentorium cerebelli was cut as close as possible to the superior petrosal sinus. The cranical nerves I–VI and the internal carotid arteries were bisected, upon which the cerebral hemispheres could be everted further backwards.

2. Prior to further dissection the anatomy of vessels and nerves in the cerebello-pontine region was studied As to the series originating in Odense a substance with a particle size of 0 1 micron in 1 % aqueous solution (Lichtblau 2 R *Bayer*") was injected in order to facilitate identification of vessels and if possible to make photographic studies The results obtained in these experiments (unpublished data) were submitted in a lecture read to the Inter national Course in Transtemporal Microsurgery of the Internal Auditory Canal" Zürich, March 1970

3 The glial part of nerves VII and VIII was cut at the site of their entrance into the brain stem. Furthermore about 3–4 cm from the medial orifice of the internal auditory canal and the subarcuate fossa, the vascular system which enters into the temporal bone from the posterior surface of the petrosal part was cut off In order to have a sufficiently large vascular section available for the later injections part of the cerebellum was usually included The mass of tissue thus produced was cautiously covered by gauze which served as protection during removal of the temporal bones

4 Care was taken to spare the temporal bone squama while the petrosal part, portions of the mastoid process, the middle ear and the medial portion of the external auditory canal were removed. The damage thus inflicted to the base of the skull was trifling and both temporal bones could be excised

5 The specimens were immersed in physiological saline and taken to the laboratory where they either immediately or after storage in the refrigerator at about —4 C for some days were kept in a specific holder designed by the author and built by Jack Urban Urban Engineering Co Burbank California It is an advantage of this holder that it permits dissection from all angles (cf fig 2, treatise D) moreover fitting of a small platform makes it possible to keep the aforementioned mass of vessels and nerves level with the medial orifice of the internal auditory canal Fitting of another specially designed equipment for vascular injections permitted delicate manipulation and sufficient stability

6 A surgical microscope was used while a syringe was inserted into the vessel or vessels into which injections were applied All other vessels were com pressed by "micro-bulldog clamps Subsequently the injections could be applied without wasting much of the contrast medium

According to the experience gained by the author the time interval between death and removal of temporal bones as well as the interval between removal of bones and injection of contrast medium, were of no significance for the results to be obtained

8 Decalcification by an 0.7 M solution of the tetrasodium salt of EDTA, pH 7.4 at 37 Decalcification was discontinued as soon as X-ray control had showed that all calcium was eliminated, usually after decalcification for 2 or 3 months.
9 Dehydration in rising concentrations of ethyl alcohol (25 %–50 %–70 %–96 % absolute alcohol) over a period of one week.
10 Embedding in celloidine at room temperature (2 %–6 %–12 %) usually throughout 2 or 3 months, followed by hardening in 70 % ethyl alcohol for one week.
11 Mounting of specimens onto cutting blocks by means of 10 % celloidine followed by hardening in 70 % ethyl alcohol, lasted for about 1 week subsequently the blocks were cut into sections of a thickness ranging from 500 up to 800 micron. The sections tolerated storage for an unlimited time until the further processes were to be performed
12. The celloidine was removed by equal portions of ether and absolute alcohol two treatments in this fluid were generally used, each covering 2 or 3 hours
13 Clearance of sections in methyl salicylate
14 With a view to a further cutting of these thick sections into thinner ones (cf procedure described in treatise G), the aforementioned embedding in celloidine was repeated and the blocks were cut into sections measuring 7 micron
15 Additional staining by routine histochemical methods such as haematoxylin combined with periodic-acid-Schiff (PAS) or toluidine blue.

Specimens in which vessels had been reproduced by staining of the vascular walls *per se* using alkaline phosphatase reagents, were further dissected as follows:

a The bone was removed by a diamond drill until nothing but a shell of bone measuring a few millimeters across surrounded the membraneous labyrinth.
b Subsequent decalcification with R.D.O. (Trade Mark Bethlehem Steel Corp.) for 10 hours at room temperature
c Cutting on the freeze-microtome into sections measuring 25–30 micron.
d Embedding in gelatine jelly

As regards the preparation of the thick, cleared sections, the above technique has been used previously by other investigators, for instance, *Eichler* (1910) *Levin A. A.* (1964) and *Levin V. N.* (1969)

Note Application of this technique was suggested to the author by Dr. William House M.D. Los Angeles, who also supported the decalcification project by means of a grant placed at disposal at the meeting of the Otological Medical Foundation in July 1967 Specimens were forwarded to the University Clinic in Odense where the author supplemented the series with specimens into which more than one dye material had been injected.

Note The vascular nomenclature used in the ensuing chapters is the one introduced by *Axelsson* (1968)

sinus In addition the superior thyroid artery the lingual artery and the external maxillary artery were compressed. Great quantities of the contrast medium were wasted during this process and the pressure could be maintained only at a level which on an estimate ranged below 100 mm/mercury injections were applied over time intervals covering about 2 minutes During injection, the anterior and the posterior surfaces of the petrosal part of the temporal bones were observed When injections had been in progress for a few seconds the contrast medium would appear below the dura mater in the area surrounding the geniculate ganglion Injections were not discontinued until dural vessels in the posterior surfaces probably also the subarcuate artery had been filled via structures in the temporal bone Two of the temporal bones were left without a second injection via branches of the basilar artery they were to serve as controls

The entire material has been classified according to the vessel or vessels into which injections were applied as well as according to type of medium used for the injections

		Nos. of specimens
I	Injection via a.i c.a (anterior inferior cerebellar artery) Microphil	28
II.	*Injection via a i.c.a 10% gelatine suspension*	2
III	Injection via a i c.a alkaline phosphatase reagent	1
IV	Injection via the common carotid artery exclusively Microphil	1
V	Same as item IV except that a 10% gelatine suspension was used	1
VI	2 injections (1) 10% gelatine suspension into the common carotid artery (2) Microphil via a.i.c.a.	1
VII	2 injections (1) Microphil via the common carotid artery (2) Microphil via a.i c.a.	3
VIII	*2 injections (1) Microphil via the carotid artery (2) alkaline* phosphatase reagent via a.i c.a.	3
IX.	2 injections of Microphil (1) via the subarcuate artery (2) via the the internal auditory artery	2
X	*2 injections (1) Microphil via a.i.c a (2) Microphil via the* inferior petrosal sinus	1
	In total	43

7 After injection of contrast medium the specimen concerned was immersed into a 3 7 % solution of formaldehyde buffered with marble All specimens except those to which alkaline phosphatase reagent had been applied were thoroughly perfused throughout 30 minutes with an 0.5 % solution of osmic acid applied via an orifice in the superior semicircular canal and the round window As a result of this process the epithelial structures of the labyrinth and the mucous membrane of the middle ear would be stained a brownish black colour that contrasted the injected dye materials

Specimens into which Microphil and/or 10 % gelatine suspensions had been injected were prepared as follows

8. Decalcification by an 0.7 M solution of the tetrasodium salt of EDTA pH 7.4 at 37°. Decalcification was discontinued as soon as X ray control had showed that all calcium was eliminated, usually after decalcification for 2 or 3 months.
9. Dehydration in rising concentrations of ethyl alcohol (25 %–50 %– 70 %– 96 % absolute alcohol) over a period of one week.
10. Embedding in celloidine at room temperature (2 %–6 %–12 %) usually throughout 2 or 3 months, followed by hardening in 70 % ethyl alcohol for one week.
11. Mounting of specimens onto cutting blocks by means of 10 % celloidine, followed by hardening in 70 % ethyl alcohol, lasted for about 1 week. Subsequently the blocks were cut into sections of a thickness ranging from 500 up to 800 micron. The sections tolerated storage for an unlimited time until the further processes were to be performed.
12. The celloidine was removed by equal portions of ether and absolute alcohol two treatments in this fluid were generally used, each covering 2 or 3 hours.
13. Clearance of sections in methyl salicylate.
14. With a view to a further cutting of these thick sections into thinner ones (cf. procedure described in treatise G) the aforementioned embedding in celloidine was repeated and the blocks were cut into sections measuring 7 micron.
15. Additional staining by routine histochemical methods such as haematoxylin combined with periodic acid Schiff (PAS) or toluidine blue.

Specimens in which vessels had been reproduced by staining of the vascular walls *per se* using alkaline phosphatase reagents, were further dissected as follows:

a. The bone was removed by a diamond drill until nothing but a shell of bone measuring a few millimeters across, surrounded the membraneous labyrinth.
b. Subsequent decalcification with R.D.O. (Trade Mark Bethlehem Steel Corp.) for 10 hours at room temperature.
c. Cutting on the freeze-microtome into sections measuring 25–30 micron.
d. Embedding in gelatine jelly.

As regards the preparation of the thick, cleared sections, the above technique has been used previously by other investigators, for instance, *Eichler* (1910), *Levin N. A.* (1964), and *Levin V. N.* (1969).

Note. Application of this technique was suggested to the author by Dr. William House M.D. Los Angeles, who also supported the decalcification project by means of a grant placed at disposal at the meeting of the Otological Medical Foundation in July 1967. Specimens were forwarded to the University Clinic in Odense where the author supplemented the series with specimens into which more than one dye material had been injected.

Note. The vascular nomenclature used in the ensuing chapters is the one introduced by *Axelsson* (1968).

sinus In addition, the superior thyroid artery the lingual artery and the external maxillary artery were compressed Great quantities of the contrast medium were wasted during this process and the pressure could be maintained only at a level which, on an estimate, ranged below 100 mm/mercury injections were applied over time intervals covering about 2 minutes During injection, the anterior and the posterior surfaces of the petrosal part of the temporal bones were observed When injections had been in progress for a few seconds, the contrast medium would appear below the dura mater in the area surrounding the geniculate ganglion Injections were not discontinued until dural vessels in the posterior surfaces probably also the subarcuate artery had been filled via structures in the temporal bone Two of the temporal bones were left without a second injection via branches *of the basilar artery they were to serve as controls.*

The entire material has been classified according to the vessel or vessels into which injections were applied as well as according to type of medium used for the injections

7 After injection of contrast medium the specimen concerned was immersed into a 3 7 % solution of formaldehyde buffered with marble All specimens *except those to which alkaline phosphatase reagent had been applied were* thoroughly perfused throughout 30 minutes with an 0.5 % solution of osmic acid applied via an orifice in the superior semicircular canal and the round window As a result of this process, the epithelial structures of the labyrinth and the mucous membrane of the middle ear would be *stained a brownish* black colour that contrasted the injected dye materials.

Specimens into which Microphil and/or 10 % gelatine suspensions had been injected were prepared as follows

ally separates the inferior portion of the fundus in the internal auditory canal from the middle ear.

Some authors have demonstrated the presence of vascular anastomoses between intra- and extra-labyrinthine structures. For instance, anastomoses between the promontorium and the internal ear could be followed in specimens stained with osmic acid (*Politzer* 1876) and also by a study of serial histological sections (*Siebenmann, 1894*). *Zange* (1919) and *Hansen* (1967) managed to trace a few vessels which via the bone separating the basal and middle cochlear coils connected the promontorium of the middle ear with the modiolus of the inner ear. Finally *Bötner and Pivotti* (1954) and *Morujo* (1967) described anastomoses to the otic capsule via branches of the internal auditory artery; localizations of such anastomoses were not further specified.

In patients with otosclerotic foci involving the endosteal layer of the cochlear capsule, for instance, *Altmann* (1962) observed that such foci might invade the septa which separate the cochlear coils. It was emphasized in particular that the blood supply to the cochlea might be compromised if these foci penetrated into the bones separating the basal and the middle coils. *Ruedi* (1968) demonstrated the presence of venous anastomoses between otosclerotic foci and the membraneous labyrinth, in particular at the site of the basal coil. *Kelemen and Linthicum Jr* (1969) declared that hearing loss of the perception type would occur in patients in whom the basal cochlear coil, maybe also several other coils, were infiltrated by otosclerotic foci.

According to reports available in the literature, it seems as if infiltration by otosclerotic foci via the otic capsule, or via the bony shelf separating the basal and middle coils, might be responsible for a reduced cochlear function. It is also apparent from the cited literature that the bone structure of the basal coil, particularly the structure separating the basal and middle coils, occupies an exceptional position, whether considered from embryological, bone-morphological, vascular-morphological, histopathological or functional points of view.

Within the cochlear modiolus, the basal portion, i.e. the portion facing the osseous shelf by which the basal and the middle coils are separated, seems to be vascularized to a higher degree than those at more apical sites. At the former site, the cochlea is supplied mainly by the spiral modiolar artery as well as by the cochlear branch of the vestibulo-cochlear artery whereas vascularization at apical sites, via the spiral modiolar artery, is less abundant (*Axelsson* 1968). This anatomical feature intensifies further the impression that the cochlear function seems to be mainly dependent on the vascular supply to the basal coil.

Some reports have been concerned with a description of areas in the vestibular part of the labyrinth where the endosteal layer either may be absent or be very thin, thereby opening up possibilities of an anastomosing between the membraneous labyrinth and the enchondral layer of the labyrinthine capsule. *Siebenmann* (1894) observed areas of this type at the non-ampullary end of the three semicircular canals. According to *Werner (1931)*, such defective areas might develop during foetal life as a result of resorption and destruction of the convex portion of the semicircular canals during growth of the latter. In agreement with this, *Bast*

CHAPTER VII

Vascular Anastomoses Between the Membraneous Labyrinth and the Surrounding Structures

Vessels in the membraneous labyrinth of the temporal bone have hitherto been considered end-arteries which, by an endosteal capsule seem to be cut off from vessels in the surrounding bone (*Seymour* 1954 *Arslan* 1963 *Anson et al* 1966) By now however it is generally agreed that numerous vessels communicate with the surrounding tissues during foetal life and throughout the first two or three years of life namely before the endosteal layer has fully developed (*Zange* 1919 *Bast* 1942 *Levin* 1964 and *Anson et al* 1966)

As to the viability and thus the vascularization, of the endosteal layer *per se* some doubt is still prevailing. For instance, *Rius and Mendo.a* (1961) and *Ser cer and Krmpotić* (1966) declared that this layer was non viable while *Rüedi* (1963) held that the endosteal layer was supplied from a branch of the auditory artery *Zechner and Altmann* (1969) agreed with the latter in that the said layer was vascularized although poorly *Gussen* (1968) found that it might be an expression of a certain viability that the tissue lining the endosteal layer facing the membraneous labyrinth contained mesenchymal cells, including osteogenic as well as chondrogenic properties which feature might be encountered even in aged individuals

Several authors have discussed the defects which throughout life may involve certain areas of the endosteal layer Such defects might provide a possible inter communication between the membraneous labyrinth and the intermediate, more richly vascularized enchondral layer of the otic capsule These authors attached special interest to the latter sites because they might allow invasion of inflammatory processes into the membraneous labyrinth (*Politzer* 1876 *Siebenmann* 1894 *Eichler* 1910 *Zange* 1919 *Eckert Möbius* 1926 *Meyer* 1933)

In the cochlear portion of the labyrinth it is mainly a matter of bone structures which throughout the length of one coil, seem to be inserted like a coarse meshed osseous shelf between the basal and the middle coils thereby connecting modiolus with the enchondral layer of the otic capsule One of the first processes of ossifica tion to develop during foetal life originate from areas at the site of the basal portion of this bone-shelf (*Bast and Anson* 1949) The separation between the tympanic scale and the vestibular scale is initiated at this site of ossification As previously mentioned the bone structure in the basal coil of this osseous separa tion is rather loose in contrast to that at more apical sites, the structure of which is dense Basally the shelf is seen to widen until it joins with the bone area which antero-posteriorly separates the cochlea and the vestibulum while it medio-later

artery the direct extensions of the intraneural vessels of the cochlear nerve as well as via the osseous branches through which the osseous bridge between the basal and middle coils communicated with vessels in the enchondral layer of the otic capsule. Thus arterial connection with at least four different vascular areas was demonstrable, whereas the capillary system pertaining to the neural elements of the middle and apical coils presented only two affluxes and effluxes in the capillary system facing the neural elements of the middle and apical coils, namely via the spiral modiolar artery and the intraneural vessels in the acoustic nerve.

Vessels in the basilar membrane were also found to be well-filled, especially within the basal coil. It was rather remarkable that vessels in the basilar membrane were filled even in areas where disappearance and degeneration of internal and external hair cells in the organ of Corti, reproduced by means of osmic acid, were of severe degree. The feature was in evidence for instance in the temporal bones from old patients with presbycousis.

Owing to the fact that degrees of filling differed greatly from specimen to specimen and that the relative filling might differ in medial cochlear structures (modiolus and basilar membrane) and lateral cochlear structures (vascular stria) it proved impossible to draw any conclusions concerning the distribution of passable vessels in structures of the middle scale in patients of different ages. On the other hand, numerous parallel capillary anastomoses between the vascular stria and the basilar membrane, by way of Reissner's membrane, were in evidence in a temporal bone from an about 90-year-old patient; a yellow dye material, grain size about 0.5 micron, suspended in gelatine solution had been injected into the bone via the common carotid artery (cf. fig. 6 in treatise II.)

B. *Anastomoses via the endosteal layer between the membraneous cochlea and the otic capsule*

The vascular anastomoses were found to be of two types (and two calibres), one in the form of osseous branches of calibres approximating those of arterioles and originating either from radiating arterioles of the vestibular scale or communicating with the collecting venules of the tympanic scale, the other in the form of nutritional canals or capillaries of especially small calibres, interspersed in the dense network of osseous lamellae in the endosteal layer.

These "rami ossiculorum arteriolae rectae" were demonstrable in 15 specimens. Each specimen contained only few (1–3) which all were of the same calibre as the radiating arterioles from which they emerged. They might emerge from any site throughout the course of the latter, even from sites at which they joined with the capillary system of the vascular stria. The anastomoses were evenly distributed over the cochlear coils.

In 14 bones, the injected medium had penetrated into spaces (calibres less than 1 micron) between the web-like system of osseous lamellae in the endosteal layer. Mostly it was seen at the level of the apical and the middle coils. In some specimens, the dye material had penetrated via the long and tortuous pathway

(1942) observed the occurrence of such resorption peripherally in the semicircular canals

Several authors, for instance *Manasse* (1905) and *Zange* (1919) observed a strand of connective tissue between the ampullae of the posterior semicircular canal and the tympanic recess close to the round window Indeed, this might be another site through which inflammatory processes might have access and where vascular anastomoses between the membraneous labyrinth and its surroundings could be found.

Author's experiments and results

The results obtained have been described and discussed as follows in treatise E.

A Anastomosis directly uniting the membraneous cochlea and the enchondral layer

Among the 40 bones which were cut into sections of a thickness ranging between 500 and 800 micron, 31 presented anastomoses of arteriolar calibre via the osseous shelf by which the basal cochlear coil is separated from the middle coil, namely anastomoses between modiolus and the enchondral layer of the otic capsule

In all 31 cases, the injected medium was seen to penetrate to this level, or further apically in the cochlea In the remaining nine specimens, injection was very sparse and the injected dye material failed to reach into the said area of the cochlear capsule

The above mentioned anastomosing vessels into which injections were applied were arteries as well as veins which individually intercommunicated with the capillary plexus surrounding the cochlear spiral ganglion The anastomoses emerged either directly from the spiral modiolar artery or they communicated directly with the two large spiral veins at other sites, however a middle piece might be inserted Such a middle piece could be seen to unite with arterioles to the basilar membrane structures radiating arterioles to the vascular stria, and furthermore anastomosing vessels of arteriolar calibre which emerged directly into the enchondral layer of the osseous capsule Arterio-venous intercommunications were also demonstrable in the modiolus at the base of the aforementioned anastomoses between modiolus and the otic capsule Thus, the pattern by which the vascular system united the modiolus with the enchondral layer appeared to be highly polymorphous In each specimen, the number of vascular anastomoses of arteriolar calibre ranged, roughly between five and ten the number of vessels into which contrast medium was injected and that of identifiable vessels stained by osmic acid have been added

The following features emerged from a more detailed analysis of the modiolar vascular system axially to the ingress or egress of the osseous anastomoses, including the capillary plexus surrounding the cochlear spiral ganglion At basal sites of the modiolus, afflux and efflux progressed via the following groups of vessels, the spiral modiolar artery the cochlear branch of the vestibulo-cochlear

artery the direct extensions of the intraneural vessels of the cochlear nerve as well as via the osseous branches through which the osseous bridge between the basal and middle coils communicated with vessels in the enchondral layer of the otic capsule. Thus arterial connection with at least four different vascular areas was demonstrable, whereas the capillary system pertaining to the neural elements of the middle and apical coils presented only two affluxes and effluxes in the capillary system facing the neural elements of the middle and apical coils, namely via the spiral modiolar artery and the intraneural vessels in the acoustic nerve.

Vessels in the basilar membrane were also found to be well-filled, especially within the basal coil. It was rather remarkable that vessels in the basilar membrane were filled even in areas where disappearance and degeneration of internal and external hair cells in the organ of Corti, reproduced by means of osmic acid, were of severe degree. The feature was in evidence for instance in the temporal bones from old patients with presbycousis.

Owing to the fact that degrees of filling differed greatly from specimen to specimen and that the relative filling might differ in medial cochlear structures (modiolus and basilar membrane) and lateral cochlear structures (vascular stria) it proved impossible to draw any conclusions concerning the distribution of passable vessels in structures of the middle scale in patients of different ages. On the other hand, numerous parallel capillary anastomoses between the vascular stria and the basilar membrane by way of Reissner's membrane were in evidence in a temporal bone from an about 90-year-old patient a yellow dye material, grain size about 0.5 micron, suspended in gelatine solution had been injected into the bone via the common carotid artery (cf. fig. 6 in treatise E.).

B. Anastomoses via the endosteal layer between the membraneous cochlea and the otic capsule

The vascular anastomoses were found to be of two types (and two calibres), one in the form of osseous branches of calibres approximating those of arterioles and originating either from radiating arterioles of the vestibular scale or communicating with the collecting venules of the tympanic scale, the other in the form of nutritional canals or capillaries of especially small calibres, interspersed in the dense network of osseous lamellae in the endosteal layer.

These "rami ossiculorum arteriolae rectae" were demonstrable in 15 specimens. Each specimen contained only few (1–3) which all were of the same calibre as the radiating arterioles from which they emerged. They might emerge from any site throughout the course of the latter even from sites at which they joined with the capillary system of the vascular stria. The anastomoses were evenly distributed over the cochlear coils.

In 14 bones, the injected medium had penetrated into spaces (calibres less than 1 micron) between the web-like system of osseous lamellae in the endosteal layer. Mostly it was seen at the level of the apical and the middle coils. In some specimens, the dye material had penetrated via the long and tortuous pathway

(1942) observed the occurrence of such resorption peripherally in the semicircular canals

Several authors, for instance *Manasse* (1905) and *Zange* (1919) observed a strand of connective tissue between the ampullae of the posterior semicircular canal and the tympanic recess close to the round window Indeed this might be another site through which inflammatory processes might have access and where vascular anastomoses between the membraneous labyrinth and its surroundings could be found

Author s experiments and results

The results obtained have been described and discussed as follows in treatise E.

A Anastomosis directly uniting the membraneous cochlea and the enchondral layer

Among the 40 bones which were cut into sections of a thickness ranging between 500 and 800 micron 31 presented anastomoses of arteriolar calibre via the osseous shelf by which the basal cochlear coil is separated from the middle coil *namely anastomoses between modiolus and the enchondral layer of the otic capsule*

In all 31 cases, the injected medium was seen to penetrate to this level or further apically in the cochlea In the remaining nine specimens injection was very sparse and the injected dye material failed to reach into the said area of the cochlear capsule

The above mentioned anastomosing vessels into which injections were applied were arteries as well as veins which individually intercommunicated with the capillary plexus surrounding the cochlear spiral ganglion The anastomoses emerged either directly from the spiral modiolar artery or they communicated directly with the two large spiral veins at other sites, however a middle piece might be inserted Such a middle piece could be seen to unite with arterioles to the basilar membrane structures radiating arterioles to the vascular stria and furthermore anastomosing vessels of arteriolar calibre which emerged directly into the enchondral layer of the osseous capsule Arterio-venous intercommunications were also demonstrable in the modiolus at the base of the aforementioned anastomoses between modiolus and the otic capsule Thus the pattern by which the vascular system united the modiolus with the enchondral layer appeared to be highly polymorphous In each specimen the number of vascular anastomoses of arteriolar calibre ranged roughly between five and ten the number of vessels into which contrast medium was injected and that of identifiable vessels stained by osmic acid have been added

The following features emerged from a more detailed analysis of the modiolar vascular system axially to the ingress or egress of the osseous anastomoses including the capillary plexus surrounding the cochlear spiral ganglion At basal sites of the modiolus, afflux and efflux progressed via the following groups of vessels. the spiral modiolar artery the cochlear branch of the vestibulo-cochlear

While supplies of blood are most abundant and rates of metabolism highest in the basal cochlear coil, the structures at this site apparently are the ones most sensitive to circulatory disturbances as compared with structures of the more apical coils. This feature has been observed in experiments on guinea pigs exposed to venous obstruction (*Kimura and Perlman* 1956) coagulation of the anterior inferior cerebellar artery (*Kimura and Perlman*, 1958), and obstruction for 30 minutes of the above mentioned arteries and subsequent re-establishment of the circulation (*Perlman Kimura and Fernandez*, 1959).

Whether the observed vascular anastomoses between structures of the membraneous labyrinth and the otic capsule may be of value for the preservation of the integrity of the membraneous structures cannot be judged until it has been defined in greater detail how these anastomoses come into communication with vessels outside the otic capsule for instance, vessels originating from the carotid arteries. The results obtained in studies of these vascular communications are submitted and discussed in chapter VIII

traversing the endosteal layer finally combining with the vascular system of the enchondral layer

In bones in which the medium had been injected via carotid arteries, it could be traced to the endosteal layer which was entered from external aspects thence it would progress further into structures of the membraneous labyrinth, a feature to be discussed in greater detail in the following chapter

C Anastomosis between the membraneous labyrinth and the osseous capsule in the vestibular portion of the labyrinth

In 16 of the temporal bones into which medium had been injected, such direct vascular intercommunication was demonstrable in the non-ampullary part of the superior semicircular canal where the endosteal layer either was very thin or non-existent. In the lateral semicircular canal, however this type of anastomosis was observed only in one specimen

In five specimens, the dye material had penetrated into the fibrous strands by which the ampullae of the posterior semicircular canal communicate with the tympanic cavity

As mentioned in chapter VI injections of grained dye materials were in all cases followed by perfusion of the labyrinth via an orifice in the superior semicircular canal or via the round window (perfusion with 0.5 % osmic acid for 30 minutes) The osmic acid had reproduced the said anastomoses to an extent by far greater than that otherwise obtainable by injection of grained dye material

It should be stressed that the degree of filling to be obtained in these vascular areas was independent of the age of the individuals from whom the specimens were obtained.

Discussion and conclusion

In specimens where the contrast medium had penetrated to the loosely built bridge separating the basal and the middle cochlear coils anastomoses of arteriolar calibres were in all cases found to communicate directly with the enchondral layer of the otic capsule Moreover throughout the cochlear coils, vessels of arteriolar calibre emerged from the radiating arterioles of the vestibular scale or they anastomosed with the collecting venule of the tympanic scale hence the vascular system in the cochlea cannot be considered composed of end-arteries.

The fact that the basal cochlear coil is the site at which anastomosing is most readily established is in further support of the findings by *Axelsson* (1968) who observed that the vascular supply to the modiolus is more abundant in the basal than in the more apical coils.

These anatomical features can be related to those encountered in experiments on guinea pigs in which the consumption of energy in the individual cochlear coils was estimated In experiments of this type *Meyer zum Gottesberge and collaborators* (1965) and *Rauch* (1967) found the rate of metabolism to be highest in the basal coil gradually decreasing towards the apical coil.

While supplies of blood are most abundant and rates of metabolism highest in the basal cochlear coil, the structures at this site apparently are the ones most sensitive to circulatory disturbances as compared with structures of the more apical coils. This feature has been observed in experiments on guinea pigs exposed to venous obstruction (*Kimura and Perlman* 1956), coagulation of the anterior inferior cerebellar artery (*Kimura and Perlman*, 1958) and obstruction for 30 minutes of the above mentioned arteries and subsequent re-establishment of the circulation (*Perlman Kimura and Fernandez*, 1959)

Whether the observed vascular anastomoses between structures of the membraneous labyrinth and the otic capsule may be of value for the preservation of the integrity of the membraneous structures cannot be judged until it has been defined in greater detail how these anastomoses come into communication with vessels outside the otic capsule, for instance, vessels originating from the carotid arteries. The results obtained in studies of these vascular communications are submitted and discussed in chapter VIII

Re item B

Nager (1954) described the vascular communication between the subarcuate artery and the vascular system of the middle ear; the latter system is considered to belong to the carotid system.

Using arteriographic techniques *Djupesland* (1970) managed, in one patient, to trace vessels from the basilar arterial system, via the osseous substance of the temporal bone, to the vascular system in the neck.

Re item C

According to some authors, the course of vessels could be traced from the membraneous cochlea to the middle ear promontorium (*Politzer* 1876, *Siebenmann*, 1894 and *Zange* 1919). Such anastomoses, however, are apparently rare.

In a preliminary report on the results obtained by micro-injections into the vascular structures of the temporal bone, *Hansen* (1967) described a technique to be used for dissection: the technique included the drilling away of osseous structures immersed into 70 % ethyl alcohol, using a stand which produced a certain transillumination of the specimen, thus, vessels into which injections had been applied could be seen to extend from the promontorium directly to structures of the basal cochlear coil. The author did not find the technique sufficient to be used for a systematic analysis of the vascular pattern in larger numbers of temporal bones and therefore preferred the conventional histological method, as mentioned in chapter VI (Material and Methods).

The results obtained have been discussed in greater detail in treatise F.

Author's studies and results

The series of 43 temporal bones is identical with the series discussed in chapter VII (Vascular anastomoses between the membraneous labyrinth and surrounding structures). As previously mentioned, all bones were studied consecutively irrespective of degrees of vascular filling. In addition to the morphological data thus obtained concerning the pattern of injections into vessels, it was possible also to decide whether contrast medium penetrated into some areas of bone more readily than into others.

In an attempt to demonstrate vascular intercommunication between extra- and intra-cranial vessels, between various branches from large vessels known to supply the temporal bone, and between arteries and veins, differently coloured contrast media were injected into one and the same bone via different vessels. At the same time it was possible to determine whether cochlea is supplied via extra-cranial vessels as well as via intra-cranial vessels.

Re item A

In table 3, a parallel is drawn between the degree of filling in one of the areas which according to *Eckert Möbius* (1926) is particularly rich in vessels, namely

CHAPTER VIII

Vascular Anastomoses Within Osseous Structures of the Temporal Bone

In this chapter it is attempted to illustrate the various problems involved in the *anatomy normal as well as pathological of the otic capsule with special* regard to the further course through the latter of the established vascular anastomoses to the membraneous labyrinth (cf chapter VII)

The following topics shall be discussed

A *Is vascularization particularly rich in some areas of the otic capsule?*
B Is it possible to demonstrate anastomoses between the extra and intra-cranial vessels which supply the otic capsule? Between individual branches emerging from larger vessels from which branches extend to the temporal bone? Between arteries in the bone substance and the venous sinuses?
C *Are the membraneous labyrinth, the more remotely situated structures of the* temporal bone, and the extra-cranial vessels in vascular communication via the vascular system in the otic capsule?

These topics have according to the available literature been discussed on few occasions only and discussions have mainly been concerned with the pathways which inflammatory processes might follow in their course through the otic capsule (*Politzer* 1876 *Siebenmann* 1894 *Zange* 1919 *Eckert Möbius* 1926 *Meyer* 1933 *Wullstein* 1948 and *Bast and Anson* 1949)

Re Item A

On the basis of a compendium including a review of previously published studies *as well as on the basis of personal studies Eckert Mobius (1926) and later also Bast and Anson* (1949) demonstrated how a richly vascularized connective tissue invades the primitive cartilage of the temporal bone during foetal life *Eckert Möbius* paid particular attention to two areas namely one surrounding the semi circular canals (supplied by branches from the subarcuate artery) the other comprising vessels the course of which extended from the complex of the internal auditory artery to the osseous zone separating the cochlea from the vestibulum in the antero-posterial direction and the internal auditory canal from the promontorium of the middle ear in the medio-lateral direction In the early literature this zone was termed 'Cozzolino s zone' according to *Eckert-Mobius* it is particularly rich in vessels and connective tissue even at late stages during life

it was possible also to follow via the bone substance, the course of vessels from the subarcuate artery and from branches of the internal auditory artery right to the carotid canal. Calibres of these vascular anastomoses were similar to those of arterioles. Furthermore, injections directly into carotid branches made it possible to trace vessels, the courses and calibres of which parallel the former although injections had been applied via the opposite end.

Two dye materials were injected into each of seven specimens, the first being injected via carotid branches, the other via branches of the anterior inferior cerebellar artery (Groups VI, VII, and VIII in chapter VI): the differently coloured media in all cases were found to coincide in vascular lumina the calibres of which were estimated to parallel those of arterioles. This phenomenon is most frequently encountered in the enchondral layer of the otic capsule but indeed, contrast media appeared also in vessels of the endosteal layer as well as in those in the periosteal layer. The dye materials are traceable from one vascular area to another even though passage through the capillary system is escaped.

Vascular anastomoses of this type were demonstrable in temporal bones from patients in all age groups.

In two specimens, dye materials of different colours had been separately injected, one via the subarcuate artery the other via branches of the internal auditory artery (group IX, chapter VI): the dye materials were seen to penetrate into one and the same vascular segment, still escaping passage through the capillary system.

Furthermore, if a dye material of one colour was injected *into* basilar artery vessels in one specimen already removed from the body and a dye material of a different colour later was injected into the inferior petrosal sinus arterio-venous shunts of arteriolar calibre would be observed (group X, chapter VI).

Thus, experimental vascular injections of this type made it possible to obtain an impression of a profuse vascular system in which flow between extra- and intracranial vessels was unobstructed: the same applies to flows between arteries and venous sinuses in the petrosal part, namely via anastomoses of arteriolar calibre.

Re Item C.

Since the above mentioned vascular plexus in the otic capsule apparently is well suited for injections to be applied to temporal bones from patients in all age groups it was possible to demonstrate a vascular intercommunication between intralabyrinthine vessels and vessels in the otic capsule, even further to the lumen in the carotid canal and the vascular system of the promontory of the middle ear in analogy with features described in chapter VII.

The latter type of anastomoses could be followed in 16 specimens, all of which were well-filled with contrast media. In five of these specimens, one single, thick, cleared section proved sufficient for the tracing of the vascular anastomoses from the basal cochlear coil, via the "vascular key area" to the vascular network of the promontorium. Besides, in one of these specimens, vessels emerging from radiating arterioles and extending directly to the vascular system of the middle ear were also demonstrable. In other words, anastomosing vessels can be traced

the "Cozzolino zone" and the degree of filling throughout the remaining part of the otic capsule The table is identical with table 1 in treatise F The term "vascular key area has substituted that of "Cozzolino s zone" because the vascular supply in this area is known to be particularly rich in the present study it includes the *osseous separation between the basal and middle coils* in other words, the area in which anastomoses between the cochlea and the otic capsule were found to be most abundant (chapter VII)

Table 3

		Degree of filling within the vascular key area as compared with filling in other parts of the capsule			Total
		Optimum	Equal	Poor	
Degree of filling in a.i.c.a. ( ) branches	Via internal auditory artery optimum	13	5	0	18
	Via subarcuate artery· optimum	1	not filled 3		6
	Degree of filling: equal	4	5	0	9
Injections into branches of the carotid artery exclusively		1	1	0	
Two injections, (1) via the carotid artery (2) via branches of a.i.c.a. (*)		4	0	0	4
Total		23	14		39

( ) anterior inferior cerebellar artery

The degree of filling within the various areas of the otic capsule.

Among the temporal bones those derived from old patients were found to be best filled even though the latter might have been suffering from generalized arteriosclerosis. Thus in the present series, the degree of filling of vessels in the otic capsule seemed to be independent of the age of the individuals.

In excess of the 'vascular key area" the area surrounding the vestibular semicircular canals appeared to be especially well filled the latter applies in particular to specimens filled via the subarcuate artery

Hence certain areas of the otic capsule were found to be particularly easy to fill by injection of contrast medium

Re Item B

In 13 well-filled specimens into which one dye material had been injected via the anterior inferior cerebellar artery vessels could be traced throughout their course from the subarcuate artery to the promontory of the middle ear In these specimens

in temporal bones from senile patients and in bones from much younger individuals. These authors held also that the rate of metabolism in bone structures in temporal bones ranged at a level higher than that in any other bone in the body

The ratio of blood volumes in the otic capsule to volumes in the membraneous labyrinth was studied in guinea pigs by *Morizono* (1968) Radioactive chrome (Cr^{51}) served as tracer Accordingly 85 % of the blood volume in temporal bones was found to be localized to the osseous capsule while no more than 15 % was localized to intralabyrinthine sites.

Many of the previously published experiments as well as the results obtained by the author of these presents seem to indicate that the otic capsule is composed of bone which is particularly well-provided with vessels and in which the rate of metabolism is high, even in very old patients.

The conclusion to be drawn is therefore that possibilities of additional and considerable vascular supplies to the membraneous parts of the labyrinth, via the otic capsule are in evidence in all individuals no matter their age

from the membraneous cochlea to the middle ear via two or three layers of the otic capsule (namely· the endosteal layer the enchondral layer and the periosteal layer) As to the last mentioned the periosteal layer the course of vessels through this could be seen to proceed via the so-called "periosteal pins" i e. vessels running perpendicular to the surface of the promontory of the middle ear until they join the vascular system in the enchondral layer

In two specimens into which differently coloured dye materials were applied into extra as well as intra-cranial vessels (one specimen from group VI and one from group VII chapter VI) contrast media of either colour were found to appear in all layers of the otic capsule as well as in all cochlear structures, includ ing the modiolus, the basilar membrane and the lateral membraneous cochlear structures the same applies to all cochlear coils. In addition, the contrast medium injected via the carotid artery was found to invade the vascular system of the membraneous labyrinth via the otic capsule most profusely via the "vascular key area The same phenomenon was encountered in two control specimens into which the media had been injected exclusively via the common carotid artery (groups IV and V chapter VI)

Discussion and conclusion

In excess of the anastomoses in the otic capsule and those between the otic capsule and the membraneous labyrinth demonstrated by means of injections using granular media or alkaline phosphatase reagents numerous other vessels of these types were visualized by means of stain ng with osmic acid

In perfectly filled specimens, even in some originating from old patients suffering from generalized arteriosclerosis, the vascular capacity via vessels in the internal auditory canal seemed equal to that of all demonstrable anastomoses between the cochlea, directly through the various layers of the otic capsule and into remote vascular areas Hence the demonstrable vascular supply via the otic capsule is apparently of value for the cochlear nutrition, it may even be of value for its structural integrity whenever the blood supply to cochleae via vessels through the internal auditory canal is compromised

The vascularity *per se* in the osseous substance of the otic capsule has been an object of discussion in the literature

According to some authors, e g. *Rius and Mendoza* (1961) *Sercer and Krmpotić (1966)* and *Mendoza and Rius* (1967) this vascularization was rather poor even insufficient and might be responsible for a development of necrotic bone processes to be encountered in all patients, no matter their age

Against this argues the fact that *Gussen* (1968) by means of celloidine sections and conventional staining methods, found the otic capsule to be a site of a vivid bone construction and decomposition throughout life The latter finding has been verified by *Zechner and Altmann* (1969) who studied the enzymatic activity of the same structures in temporal bones from patients in different age groups They observed that concentrations of acid mucopolysaccharides were almost identical

sels were in all cases filled with "Micropill" or with a grained dye material suspended in 10 / gelatine. In the remaining 10 cases, vessels in the acoustic nerves were either insufficiently filled (six out of the 10) or they had been reproduced by staining of the vascular walls, using alkaline phosphatase reagent (four out of the 10). It proved impossible to judge the pattern on the basis of freeze-sections of the acoustic nerve and consequently these specimens are not included in the final survey

In 24 out of the 33 specimens studied, injections managed to fill the Schwann part as well as the glial part of nerves. Filling was optimum in the Schwann part in all cases. In the remaining nine specimens, satisfactory filling was obtained only in one of the two parts. In two out of these 24 specimens, two dye materials were used for the reproduction of the intraneural vessels they were injected via the anterior inferior cerebellar branches and carotid branches respectively Both dye materials coincided in one and the same vascular segment within all zones of these nerves

Dye materials injected via anterior inferior cerebellar branches were seen to penetrate into the intraneural branches, either via branches arising from this main stem or via branches from the internal auditory arteries finally filling via vessels which united the dura in the internal auditory canal with the epineurium also was achieved

The vascular pattern, calibres of vessels, and vascular density in the Schwann part seemed to be uniform, no matter the age of patients. The pattern might appear in the form of rectangular loops composed of longitudinal vessels of arteriolar calibre, or pre-capillary calibre they were also seen to be composed of the interspersed transverse vessels. If counted over the diameter of nerves, an average of 15 to 20 such meshes would be in evidence.

The vascular density is considered to be identical at axial sites and at the more superficial sites in the Schwann part, no matter the age of patients. The nerve arises from the modiolus, emerging through tractus spiralis foraminosus, at which site an apparently high number of vessels is seen to enter into and emerge from the basal coil superficially in the nerve this was true even in specimens *originating* from old patients with generalized arteriosclerosis.

In the glial parts of nerves, i.e. in the transitional zone as well as in more centrally situated zones, nothing but longitudinal vessels were in evidence as it had proved impossible to apply injections into transverse vessels. Such longitudinal vessels are often direct continuations of those in the Schwann part.

Two nerves belonging in this series, i.e. those in which filling of the vascular system was optimum, were re-embedded in celloidine and cut into serial sections measuring 7 micron additional staining included haematoxylin-PAS. In similarity with findings in the thick, cleared sections vascularization seemed to be most dense in the Schwann part. Furthermore, the vascular density at axial and peripheral sites seemed to be identical in all parts of the nerves.

Owing to the deficient filling in glial parts of the nerves it might be difficult to determine the ratio of numbers of vessels in patients in one age group to numbers of vessels in patients in other age groups.

CHAPTER IX

The Vascular Supply in Various Parts of the Cochlear Nerve

The cochlear nerve like other nerves consists of a Schwann part and a glial part.

Němeček et al (1969) *have reviewed the relevant literature* on the histological histochemical and ultrastructural appearance of the cranial nerves In addition, they have submitted the results obtained in studies focused mainly on the "transitional zone" i e a narrow zone of the glial part of the nerve adjacent to the Schwann part. This monograph shall be briefly outlined

The nerve was found to be thickest peripherally in the Schwann part in which the supporting cells are Schwann's cells and vascularization is strikingly more abundant than in the glial part.

The glial part of the nerve consists of two parts, namely the so-called transitional zone and a more centrally situated glial zone Supporting cells in the transitional zone represent a variation of the oligodendroglial cells in the central nervous system they are of the so-called Hortega IV type, the external shape of which may remind of that of Schwann's cells their internal structure being identical with that of oligodendroglial cells Accordingly these cells are termed schwannoid cells" The rate of metabolism in the transitional zone is higher than rates otherwise observed in the nerve not infrequently it has been considered an element in the so-called glial barrier" surrounding the central nervous system The supporting cells at more central sites of the glial nerve are oligodendroglial cells as regards their structure it does not deviate much from that of supporting cells otherwise encountered in the white matter of the central nervous system

Takahashi (1966) compared the degenerative changes in the Schwann part of a cranial nerve (the vagus nerve) with changes in identical parts of nerves in the sympathetic nervous system and in one nerve in the extremities (the sciatic nerve) In specimens obtained from patients with severe generalized arteriosclerosis, the peripheral nerve was found to be a site of severe pathological changes whereas changes were moderate in the Schwann part of the sympathetic nerves and in the vagus nerve

The arteriosclerotic lesions in extra-cranial nerves have been described in greater detail, for instance by *Cottrell* (1940) *Eames and Lange* (1967) and *Ochoa and Mair* (1969)

Author's studies and results

In 33 temporal bones out of 43 intraneural vessels of the vestibulo-cochlear nerve were filled to a degree sufficient to allow a judgement of the vascular pattern Ves

sels were in all cases filled with "Microphil" or with a grained dye material suspended in 10 % gelatine. In the remaining 10 cases, vessels in the acoustic nerves were either insufficiently filled (six out of the 10) or they had been reproduced by staining of the vascular walls, using alkaline phosphatase reagent (four out of the 10). It proved impossible to judge the pattern on the basis of freeze-sections of the acoustic nerve and consequently these specimens are not included in the final survey.

In 24 out of the 33 specimens studied, injections managed to fill the Schwann part as well as the glial part of nerves. Filling was optimum in the Schwann part in all cases. In the remaining nine specimens, satisfactory filling was obtained only in one of the two parts. In two out of these 24 specimens, two dye materials were used for the reproduction of the intraneural vessels: they were injected via the anterior inferior cerebellar branches and carotid branches, respectively. Both dye materials coincided in one and the same vascular segment within all zones of these nerves.

Dye materials injected via anterior inferior cerebellar branches were seen to penetrate into the intraneural branches, either via branches arising from this main stem or via branches from the internal auditory arteries; finally, filling via vessels which united the dura in the internal auditory canal with the epineurium also was achieved.

The vascular pattern, calibres of vessels, and vascular density in the Schwann part seemed to be uniform, no matter the age of patients. The pattern might appear in the form of rectangular loops composed of longitudinal vessels of arteriolar calibre, or pre-capillary calibre: they were also seen to be composed of the interspersed transverse vessels. If counted over the diameter of nerves, an average of 15 to 20 such "meshes" would be in evidence.

The vascular density is considered to be identical at axial sites and at the more superficial sites in the Schwann part, no matter the age of patients. The nerve arises from the modiolus, emerging through tractus spiralis foraminosus, at which site an apparently high number of vessels is seen to enter into and emerge from the basal coil superficially in the nerve: this was true even in specimens originating from old patients with generalized arteriosclerosis.

In the glial parts of nerves, i.e. in the transitional zone as well as in more centrally situated zones, nothing but longitudinal vessels were in evidence as it had proved impossible to apply injections into transverse vessels. Such longitudinal vessels are often direct continuations of those in the Schwann part.

Two nerves belonging in this series, i.e. those in which filling of the vascular system was optimum, were re-embedded in celloidine and cut into serial sections measuring 7 micron; additional staining included haematoxylin-PAS. In similarity with findings in the thick, cleared sections, vascularization seemed to be most dense in the Schwann part. Furthermore, the vascular density at axial and peripheral sites seemed to be identical in all parts of the nerves.

Owing to the deficient filling in glial parts of the nerves it might be difficult to determine the ratio of numbers of vessels in patients in one age group to numbers of vessels in patients in other age groups.

At the line of demarcation between the Schwann part and the glial zone of transition the vascular pattern changed abruptly from the type observed in the Schwann part into that seen in the glial parts This feature was observed in nerves from patients in all age groups

Discussion and conclusion

The vascular density throughout the Schwann part of the 8th cerebral nerve was found to be uniform in all specimens, no matter the age of patients. This is in conformity with the findings obtained by *Takahashi* (1966) in a study of the vagus nerve and the sympathetic nerves

The apparently large number of vessels to pass through that part of tractus spiralis foraminosus which leads to structures in the basal cochlear coil is not commensurate with data submitted by *Krmpotić* (1969) who declared that the foramina in tractus spiralis foraminosus would occlude late in life according to this author a strangulation of vessels and nerves entering into the structures of the basal cochlear coil might thus be one of the factors responsible for the development of presbycousis

The abrupt shifting from the dense and regular vascular patterns in the Schwann part to the less dense pattern or rather a vascular system into which injection had been more sparse seen in the transitional zone and other zones in the glial nerve, is in agreement with findings obtained by *Němeček et al* (1969)

As regards the severity of the degenerative changes, it should be mentioned that a similar abrupt shifting at the line of demarcation between the Schwann part and the glial part of the 8th cranial nerve has been observed in patients with generalized arteriosclerosis involving the main ramifications of the anterior inferior cerebellar artery in the internal auditory canal (patients in group I chapter IV) in these patients the lesions involving the Schwann part were found to range between mild and moderate degrees whereas changes in the glial parts of the nerve were considered to be severe even monstrous (approximately like those observed in the white matter of the cerebral hemispheres) (*Hansen and Reske-Nielsen* 1965)

CHAPTER X

Summary and Discussion of Clinical and Anatomical Findings

The clinical findings together with the patho-anatomical and normo-anatomical studies are summed up and discussed in chapter X. The object of the study has been to illustrate, even to define if possible, the aetiology involved in certain types of perceptive hearing loss, particularly that to develop late in life.

Re Part I

Temporal bones and brains from 14 patients have been exposed to microscopic study the histological findings have tentatively been correlated with those obtained by clinical and otological examination as well as by pure-tone audiometry

Examination of the patient discussed in chapter II (abstract of treatise A. Cortical Hearing Loss in a Patient with Glioblastoma) shows that the hearing capacity may vary parallel with cerebral lesions exclusively in the present case, oedema has been found to involve the cerebral hemispheres moreover the loss of hearing is found to be of the presbycousis type.

Chapter IV is an abstract of treatise B Pathological Studies in Presbycousis. Cochlear and Central Findings in 12 Aged Patients. The following conclusion is drawn. In 11 of the patients, the loss of hearing applies to the high-frequency range as well as to the low-frequency range the loss of hearing of tones in the high-frequency range seems to be attributable to lesions involving central as well as peripheral sites while the loss of hearing of tones in the low-frequency range seems to be due to lesions at cerebral sites exclusively the apical and middle coils remaining intact in the latter cases or the pathological changes might be slight only Among these 11 patients, the one in group IV is included though the lesion applies only to the right ear The hearing loss of classic presbycousis type in one patient (group III) is explicable only as a consequence of changes affecting the acoustic nerves and the brain since the cochlea is found to remain normal in this patient.

In chapter V (abstract of treatise C. Pathological Studies in Perceptive Deafness. A Patient with Hydrops of the Labyrinth) a patient is discussed in whom Ménière's disease arteriosclerosis, and loss of hearing of tones of all frequencies are diagnosed The hearing loss may have been due to pathological processes at peripheral as well as central sites.

Distribution of the pathological processes involving the cochlea and the cerebrum varies greatly from patient to patient, this seems particularly notable in the cases of patients suffering from presbycousis in whom the cochlear structures remain either intact or slightly to moderately altered as compared with the often severe

At the line of demarcation between the Schwann part and the glial zone of transition, the vascular pattern changed abruptly from the type observed in the Schwann part into that seen in the glial parts This feature was observed in nerves from patients in all age groups

Discussion and conclusion

The vascular density throughout the Schwann part of the 8th cerebral nerve was found to be uniform in all specimens, no matter the age of patients. This is in conformity with the findings obtained by *Takahashi* (1966) in a study of the vagus nerve and the sympathetic nerves.

The apparently large number of vessels to pass through that part of tractus spiralis foraminosus which leads to structures in the basal cochlear coil is not commensurate with data submitted by *Krmpotić* (1969) who declared that the foramina in tractus spiralis foraminosus would occlude late in life according to this author a strangulation of vessels and nerves entering into the structures of the basal cochlear coil might thus be one of the factors responsible for the development of presbycousis

The abrupt shifting from the dense and regular vascular patterns in the Schwann part to the less dense pattern, or rather a vascular system into which injection had been more sparse seen in the transitional zone and other zones in the glial nerve is in agreement with findings obtained by *Němeček et al* (1969)

As regards the severity of the degenerative changes, it should be mentioned that a similar abrupt shifting at the line of demarcation between the Schwann part and the glial part of the 8th cranial nerve has been observed in patients with generalized arteriosclerosis involving the main ramifications of the anterior inferior cerebellar artery in the internal auditory canal (patients in group I chapter IV) in these patients the lesions involving the Schwann part were found to range between mild and moderate degrees whereas changes in the glial parts of the nerve were considered to be severe even monstrous (approximately like those observed in the white matter of the cerebral hemispheres) (*Hansen and Reske Nielsen* 1965)

tions to four vascular branches are established, namely to the spiral modiolar artery to the cochlear branch of the vestibulo-cochlear artery to intraneural vessels of the auditory nerve, as well as to vessels to and from the enchondral layer of the otic capsule At apical sites of the modiolus, however vascular communication is in evidence only to the spiral modiolar artery and the intraneural vessels of the auditory nerve

The abundant injections into the basal coil include also the vascular system of the basilar membrane even the vessel of the basilar membrane This feature is observed also in temporal bones derived from old patients in whom osmic acid staining of the organ of Corti discloses a coincident disappearance of hair cells there. In one such specimen it is even possible to trace grained contrast media between vessels in the basilar membrane and the vascular stria via vascular communications within Reissner's membrane at the site of the basal coil.

The further course of the vascular anastomoses through the other structures of the temporal bone is discussed in chapter VIII (abstract of treatise F Vascular Anatomy of the Human Temporal Bone. II. Vascular Anastomoses inside the Labyrinthine Capsule). It is attempted to have vessels in the otic capsule filled via basilar vessels (41 specimens) carotid vessels (10 specimens), and via both in one and the same temporal bone (8 specimens) The degrees of filling vary although variations are not dependent on ages of patients or types of grained contrast media applied

By means of such injections it is possible in 16 specimens to follow vessels in their courses between the internal ear and the middle ear throughout two or three layers of the otic capsule In addition, direct communication between carotid vessels and basilar artery branches might be demonstrable by injections into either one of these areas or into both within one and the same temporal bone In two cases, such communications are demonstrable within the cochlea where the dye materials appear in one and the same intracochlear vessel which might be one in the modiolus, in the basilar membrane, or in the vascular stria. Double-injections of this type also disclose anastomoses between separate anterior inferior cerebellar branches (the subarcuate artery and the internal auditory artery) in the bone substance *per se* Arterio-venous anastomoses of arteriolar calibre are also found to unite the inferior petrosal sinus with the arterial system. Such arterio-venous anastomoses of smaller calibres are seen to unite the vascular area of the subarcuate artery with the superior petrosal sinus

Certain areas of the osseous labyrinthine capsule which during foetal life are the sites of the most abundant penetration by connective tissue and vessels are seen to be particularly well filled with dye materials these areas are the following: the area round about the semicircular canals, particularly well-filled via the subarcuate artery branches the area between the base of the cochlea (including the osseous shelf wedged in between the middle and the basal coil), the vestibule, the fundus of the internal auditory canal, and the middle ear promontorium, particularly well-filled via the internal auditory artery branches The latter area is termed "the vascular key area by the present author while the same region is termed Corradino's zone according to *Eckert-Möbius* (1926)

cerebral lesions Intracranial vascular changes including those involving the basilar circulation and vessels in the internal auditory canal seem also to be extremely severe while structures in the peripheral auditory organ are well preserved

Inspired by the results thus obtained, the author embarked upon an experimental study of vessels in order to examine whether the relative integrity of intralabyrinthine structures might be maintained by hitherto unrecognized vessels in excess of the branches of the intracranial vascular system

Re Part 2

In 43 temporal bones obtained from 33 individuals, the vascular system has been filled to various degrees by means of a micro-injection method elaborated by the author The *composition of the material is very heterogeneous both as regards the* distribution according to age of patients and the media used for injections also the sites of injections vary the media being applied either via extra or intra-cranial vessels The techniques used for injection and dissection are described in detail in chapter VI (the description of the method used for injection is an abstract of that previously published in treatise D *Vascular Anatomy of the Human Temporal* Bone A Preliminary Report)

Coincident microscopy of the equivalent brains and injections into these have not been possible Gross inspection of brains from these old patients, however might often disclose severe, mostly sporadic vascular changes. Severe arteriosclerotic changes were also seen to involve the basilar vessels. Intracranial vessels supplying right and left temporal bones were found to deviate greatly in calibres and morphology

In chapter VII (abstract of treatise E. Vascular Anatomy of the Human Temporal Bone I Anastomoses between the Membraneous Labyrinth and its Bony Capsule) the vascular communication between the cochlea and the otic capsule is described such communications are filled with the above mentioned contrast media. In all temporal bones where the contrast media are seen to penetrate to the loosely built bone shelf between the basal and middle cochlear *coils (31 bones)*, vascular anastomoses of arteriolar calibre are found to unite the modiolus with the vascular system in the enchondral layer of the otic capsule This feature is demonstrable whether injections are applied via basilar vessels or carotid branches Furthermore vessels of calibres paralleling those of *radiating arterioles of the vestibular scale are demonstrable in 15 specimens* these vessels arise at right angles to the latter and transversing the endosteal layer they unite with the vascular system of the enchondral layer The phenomenon is seen in all of the cochlear coils Moreover in 14 specimens the contrast media are seen to penetrate between fibrils of the endosteal layer

By this means it is demonstrated that *the cochlear vessels are no end-arteries* Vascular communication between the otic capsule and the intracochlear structures is apparently especially abundant at the level of the basal coil including the vascular network *around its spiral ganglion. In this cochlear region* communica

tions to four vascular branches are established, namely to the spiral modiolar artery to the cochlear branch of the vestibulo-cochlear artery to intraneural vessels of the auditory nerve as well as to vessels to and from the enchondral layer of the otic capsule At apical sites of the modiolus, however vascular communication is in evidence only to the spiral modiolar artery and the intraneural vessels of the auditory nerve.

The abundant injections into the basal coil include also the vascular system of the basilar membrane even the vessel of the basilar membrane This feature is observed also in temporal bones derived from old patients in whom osmic acid staining of the organ of Corti discloses a coincident disappearance of hair cells there In one such specimen it is even possible to trace grained contrast media between vessels in the basilar membrane and the vascular stria via vascular communications within Reissner s membrane at the site of the basal coil.

The further course of the vascular anastomoses through the other structures of the temporal bone is discussed in chapter VIII (abstract of treatise F Vascular Anatomy of the Human Temporal Bone II Vascular Anastomoses inside the Labyrinthine Capsule) It is attempted to have vessels in the otic capsule filled via basilar vessels (41 specimens) carotid vessels (10 specimens), and via both in one and the same temporal bone (8 specimens) The degrees of filling vary although variations are not dependent on ages of patients or types of grained contrast media applied

In chapter VII (abstract of treatise E Vascular Anatomy of the Human Temporal Bone I Anastomoses between the Membraneous Labyrinth and its Bony Capsule) the vascular communication between the cochlea and the otic capsule is described such communications are filled with the above mentioned contrast media. In all temporal bones where the contrast media are seen to penetrate to the loosely built bone shelf between the basal and middle cochlear coils (31 bones) vascular anastomoses of arteriolar calibre are found to unite the modiolus with the vascular system in the enchondral layer of the otic capsule This feature is demonstrable whether injections are applied via basilar vessels or carotid branches Furthermore vessels of calibres paralleling those of radiating arterioles of the vestibular scale are demonstrable in 15 specimens these vessels arise at right angles to the latter and, transversing the endosteal layer they unite with the vascular system of the enchondral layer The phenomenon is seen in all of the cochlear coils Moreover in 14 specimens the contrast media are seen to penetrate between fibrils of the endosteal layer

By this means it is demonstrated that the cochlear vessels are no end-arteries Vascular communication between the otic capsule and the intracochlear structures is apparently especially abundant at the level of the basal coil, including the vascular network around its spiral ganglion In this cochlear region, communica

The hearing loss applying to the low-frequency range is in five patients found to exceed the level otherwise encountered in cases of presbycousis (three patients in group I, one in group IV (cf. table 1)); the fifth patient who is discussed in chapter V was suffering from Ménière's disease. It is rather difficult to decide whether a parallel can be drawn between the degree of the loss of hearing of tones in the low-frequency range and the severity of the pathological processes involving any specific site in the cerebral auditory pathways and centres. It is concluded, however, that such loss of hearing of tones in the low-frequency range mainly if not exclusively may be attributable to cerebral lesions in these senile patients (cf. chapter IV) in whom nothing but insignificant degenerative lesions are seen to involve structures of the middle and apical coils, even though degrees of such deafness may vary considerably. As regards the patient with Ménière's disease (chapter V), the histological findings suggest that the hearing loss applying to the low-frequency range might be attributable in part to the cerebral lesions.

Other investigators, for instance *Jørgensen* (1961) and *Ishii* (1967) have also observed such heterogeneous distribution of arteriosclerotic, vascular degenerative changes including the involvement of intracranial vessels and vessels in the internal auditory canal in cases in which the cochlear vessels are only moderately affected.

On the other hand, the degrees of degenerative changes in cochlear as well as cerebral neural elements have not been described before. A few authors, namely *Metzker* (1958) and *Kirikae* (1964) observed disappearance and degeneration of cells in the auditory pathways and centres of the brain stem.

In some of the patients discussed in Part 1, a distinct line of demarcation was seen to distinguish between the severe, even monstrous, changes involving the central neural elements and the moderate changes at peripheral sites, namely at the site of transition from the glial part to the Schwann part of the acoustic nerve within the internal auditory canal. *Takahashi* (1966) observed similar features in the intracranial nerves of patients with severe generalized arteriosclerosis. Morphological studies by *Němeček et al.* (1969) disclosed an equally distinct line of demarcation at the identical site in the 1st neurone of the auditory pathways. In addition, these authors found that vascularization pertaining to the peripheral Schwann part was strikingly richer than that in the glial part of the 8th nerve.

On the basis of the experimental injections described in Part 2, the author estimates that the vascular pattern is most dense within the Schwann part of the acoustic nerve; this applies even to findings in old patients.

Likewise, it emerged that the cochlea is in vascular communication with the surrounding bone structures and, in fact, is not isolated from the latter. The intracochlear structures in all coils, but mainly those in basal coils, are actually in vascular communication with extracranial areas via anastomoses of arteriolar calibre. The latter is demonstrated by injections via intra- and extra-cranial vessels as well as by coincident injections via both into temporal bones from patients in all age groups.

The fact that intracochlear structures remain well preserved even in patients

Finally the vascular pattern in the vestibulo-cochlear nerve is studied in this series of temporal bones to which injections are applied The study is described in chapter IX (abstract of treatise F Vascular Anatomy of the Human Temporal Bone III The Vascularization of the Vestibulo-Cochlear Nerve) In the peripheral part, the Schwann part, of the nerve (the term referring to the presence of Schwann's supporting cells) the vascular pattern is found to be perfectly normal in patients in all age groups

The vascular pattern is seen to change distinctly at the site of transition between the Schwann part and the glial parts of the nerve (termed according to the different types of supporting cells involved) Vascularization seems to be less rich in the glial than in the Schwann part. The same is noticed in two well filled nerves cut into serial sections of a thickness of 7 micron and stained with haematoxylin-PAS The vascular density in peripheral and axial parts of the nerves is apparently equal

Discussion

The cited literature and the most essential results obtained in the present study have formed the basis of a discussion of the aetiology involved in perceptive deafness diagnosed in the patients comprised in the author's series

It is attempted to evaluate and compare degrees of severity of the pathological processes involving the temporal bones and brains of the patients discussed in Part 1 The findings obtained suggest that the loss of hearing is attributable mainly to the cerebral lesions.

In patients in whom the degree of deafness of the presbycousis type "pertaining to age" the most severe lesions are found to involve the white matter of the cerebral hemispheres together with the glial part of the acoustic nerve (three patients in group I one in group II chapter IV (table 1 page 28))

In two cases the hearing losses are of degrees beyond that "pertaining to age" while the audiometric curves are found to be of the typical presbycousis shape In one of these patients in whom the peripheral auditory organ is intact, the most severe pathological processes involve the cerebral hemispheres (cf chapter II the data are obtained during periods when involvement of both cerebral hemispheres is manifest in the patient concerned) lesions in the other patient (group II chapter IV (cf table 1)) are found to involve the cerebral hemispheres and the acoustic nerves while the cochlea are seen to remain intact.

The loss of hearing applying to the high-frequency range is in three patients found to exceed the level otherwise encountered in cases of presbycousis (two patients in group I one in group II chapter IV (cf table 1)) The cerebral lesions are in all cases considered to be much more severe than those observed in the peripheral auditory organs Besides the cochlear changes are found to be of the same degree as those observed in cases where curves suggest presbycousis Thus the hearing loss applying to the high-frequency range and exceeding that otherwise considered typical of old age is assumed to be attributable mainly to the cerebral lesions

that this feature is demonstrable in temporal bones from patients in all age groups, it seems rather paradoxical that the ganglion cells in the basal coil are the ones which are prone to disappear and degenerate. One reason may be that metabolic waste products might accumulate mainly at this site where the blood supply is most profuse; the latter postulation is substantiated by the fact that hearing losses in old individuals are found to be attributable to nutritional factors (*Rosen and Olin*, 1965). Another explanation is suggested by *Meyer zum Gottesberge et al.* (1965) and *Rauch* (1967) according to whom the energy consumption is highest in the basal cochlear coil where also wear and tear is most marked, as demonstrated by *von Békésy* (1960) who observed that all tones would produce vibrations in the basal cochlear coil whereas the apical cochlear coils are activated exclusively by tones in the low-frequency range.

It remains open to discussion whether lesions of ganglion cells in the basal cochlear coil are contributory to the hearing losses observed in patients in the various series. In fact, *Crowe et al.* (1934), *Schuknecht* (1955) and *Citron et al.* (1963) declared that the hearing capacity may remain intact even though 50–80 % of the ganglion cells are destroyed. It should finally be emphasized again that the hearing loss of the presbycousis type diagnosed in one patient (chapter II) seems to be attributable almost exclusively to pathological processes involving the cerebral hemispheres.

The lesions in the organ of Corti (Part 1) are probably artefacts which may have developed after death. In the present study similar lesions were demonstrable in osmic acid stained preparations from old individuals (cf. Part 2); such staining served to reveal the disappearance of hair cells at the site of the basal coil; this feature is in conformity with findings obtained by *Bredberg* (1968). Furthermore, coincident injections of dye material into these specimens are seen to fill vessels in close connection with the organ of Corti, even in the region of the basal coil (Part 2, chapter VII). This is in conformity with findings obtained by *Axelsson and Ernstson* (1970) in experiments with waltzing guinea pigs in which injections were applied into the vessel of the basilar membrane.

So far it cannot be decided whether the demonstrated lesions in the organ of Corti may have contributed to the loss of hearing in the patients here discussed. In fact, the histological findings may not have been of any consequence. *Ruben* (1963) found the cochlear microphonic potential to be normal in an old patient with presbycousis. Also *Schnieder and Janzer (1969)* who exposed guinea pigs to histochemical analysis and, in addition, measured the cochlear microphonic potential as a standard of the degenerative changes to develop in the organ of Corti, found such functional measurement out of proportion to the histologically demonstrable changes induced by "white noise".

All cochlear vessels in the patients discussed in Part 1 seem to remain relatively well-preserved; also temporal bone vessels from the same sites (discussed in Part 2) are suitable for injection, no matter the age of patients.

with severe arteriosclerosis may find its explanation in this additional vascular supply to the cochlea. This opinion is formed on the basis of aa pooling of vessels into which grained contrast media is applied and of vessels reproduced by means of osmic acid perfusion Such additional supply serves also to explain why degeneration in the right and left cochleae is symmetrical in patients with presbycousis, irrespective of the marked asymmetry of vessels at the base of the brain and the uneven distribution of arteriosclerotic plaques in this vascular region The asymmetry of vessels in the basilar system has been demonstrated by *Levin* (1964) and by the present author (chapter VI)

This additional vascular supply to the cochlea suggests that bone anastomoses are of value for the nutrition of the cochlea, even in very old individuals, because the apparently dense vascular network in temporal bones from the latter are satisfactorily filled Owing to the heterogeneity of the material as regards media used for injections, sites to which injections are applied, and also the varying degrees of filling in vessels in patients in the individual age groups, it is hardly possible to draw any conclusions concerning the number of vessels which, in patients in the individual age groups, may be suitable for injection

It appears from the literature however that the rate of metabolism in bone structures of the temporal bone remains almost unchanged throughout life (*Zechner and Altmann* 1969) and also that the vascular supply is only moderately affected by arteriosclerosis in old patients (*Gusten* 1968) Even so the latter author found thrombi to be numerous in vessels in individuals in whom the severity of generalized arteriosclerosis measured by their age, was abnormal (*Gusten* 1969)

The intracochlear changes observed in the patients discussed in Part 1 are manifest mainly in the form of varying degrees of disappearance and degeneration of ganglion cells at the level of the basal cochlear coil. Any proportionality between degrees of these pathological changes and hearing losses diagnosed is not demonstrable In patients with presbycousis for instance apparently normal conditions (patient no 6 chapter IV) may alternate with a disappearance of about 75 % of the cells in other pat ents. In two patients whose hearing losses of the presbycousis type are of a severity otherwise observed in much older patients conditions seem to be normal (patient no 11 group III chapter IV and the patient discussed in chapter II whose hearing impairment occurred during periods when bilateral hemispherical changes were manifest)

This discrepancy between degrees of severity of the pathological processes and the diagnosed hearing losses has been described also by *Crowe et al* (1934) *Saxén* (1952) *Fleischer* (1956) and *Jørgensen* (1961)

By means of the vascular injections described in Part 2 it is possible to demonstrate that vessels communicating with the capillary plexus surrounding the spiral cochlear ganglion are most numerous at the site of the basal coil Vessels in direct communication with the otic capsule (chapter VII) and further progressing to extracranial areas belong to this category (chapter VIII) Taking into consideration

that this feature is demonstrable in temporal bones from patients in all age groups, it seems rather paradoxical that the ganglion cells in the basal coil are the ones which are prone to disappear and degenerate. One reason may be that metabolic waste products might accumulate mainly at this site where the blood supply is most profuse: the latter postulation is substantiated by the fact that hearing losses in old individuals are found to be attributable to nutritional factors (*Rosen and Olin* 1965). Another explanation is suggested by *Meyer zum Gottesberge et al.* (1965) and *Rauch* (1967) according to whom the energy consumption is highest in the basal cochlear coil where also wear and tear is most marked, as demonstrated by *von Békésy* (1960) who observed that all tones would produce vibrations in the basal cochlear coil whereas the apical cochlear coils are activated exclusively by tones in the low-frequency range.

It remains open to discussion whether lesions of ganglion cells in the basal cochlear coil are contributory to the hearing losses observed in patients in the various series. In fact, *Crowe et al.* (1934), *Schuknecht* (1955) and *Citron et al.* (1963) declared that the hearing capacity may remain intact even though 50–80 % of the ganglion cells are destroyed. It should finally be emphasized again that the hearing loss of the presbycousis type diagnosed in one patient (chapter II) seems to be attributable almost exclusively to pathological processes involving the cerebral hemispheres.

The lesions in the organ of Corti (Part 1) are probably artefacts which may have developed after death. In the present study, similar lesions were demonstrable in osmic acid stained preparations from old individuals (cf. Part 2): such staining served to reveal the disappearance of hair cells at the site of the basal coil; this feature is in conformity with findings obtained by *Bredberg* (1968). Furthermore, coincident injections of dye material into these specimens are seen to fill vessels in close connection with the organ of Corti, even in the region of the basal coil (Part 2, chapter VII). This is in conformity with findings obtained by *Axelsson and Ernstson* (1970) in experiments with waltzing guinea pigs in which injections were applied into the vessel of the basilar membrane.

So far, it cannot be decided whether the demonstrated lesions in the organ of Corti may have contributed to the loss of hearing in the patients here discussed. In fact, the histological findings may not have been of any consequence. *Ruben* (1963) found the cochlear microphonic potential to be normal in an old patient with presbycousis. Also *Schnieder and Janzer* (1969) who exposed guinea pigs to histochemical analysis and, in addition, measured the cochlear microphonic potential as a standard of the degenerative changes to develop in the organ of Corti, found such functional measurement out of proportion to the histologically demonstrable changes induced by "white noise".

All cochlear vessels in the patients discussed in Part 1 seem to remain relatively well-preserved; also temporal bone vessels from the same sites (discussed in Part 2) are suitable for injection, no matter the age of patients.

Furthermore the injection experiments provide evidence of a vascular communication between the vascular stria and the basilar membrane namely via Reissner s membrane

Atrophy of the vascular stria like that observed by *Schuknecht* (1955) and *Ishii* (1967) in senile patients is not encountered in any of the patients discussed in Part 1 Indeed, the vascular stria is found to be well-filled in temporal bones removed from old patients (Part 2)

Conclusion

According to the histological analysis of structures in temporal bones and brains in patients with various types of perceptive hearing impairments, such impairments as apply to the high frequency range seem to be attributable, at least partly to lesions involving cerebral sites whereas impairments applying to the low frequency range apparently are due to cerebral lesions exclusively Only the patient with Ménière s disease represents an exception

Examinations of temporal bones to which contrast media are applied seem to substantiate the hypothesis according to which arteries in the peripheral auditory organ are not end-arteries In fact, it applies to individuals in alle age groups that the cochlear vessels are found to communicate with intracranial as well as extra cranial sources The latter feature may explain why structures of the internal ear are found to be relatively well preserved in elderly patients (Part 1) in spite of the severe neurogenic and vascular anomalies encountered at the more centrally localized sites in the auditory pathways

As regards the intracochlear structures it must be admitted that there is a certain discrepancy between the particularly rich vascular supply to the basal cochlear coil and the rather severe degenerative lesions to develop within the same region As to the vascular supply to the middle cochlear scale, it should be stressed that grained contrast media are seen to penetrate right into the vessel of the basilar membrane vessels being well filled even in areas where coincident disappearance of hair cells in the organ of Corti is in evidence Furthermore these vascular injections serve to demonstrate the vascular communication between the basilar membrane and the vascular stria, via Reissner's membrane

Thus by way of a comparison of findings in ears and brains (Part 1) and by means of experimental injections into vessels of the temporal bone (Part 2) perceptive hearing impairments including the so-called "hearing loss pertaining to age is found to be mainly attributable to the pathological processes at intracranial sites

Continued research in the fields of audiology and pathology including studies of all parts of the complicated auditory system, is urgently required Such research should include examination of all structures within the temporal bones, including the otic capsule In this connection the attention shall be directed to the technique used for such injections, a technique which has been improved and elaborated by

the author this technique is combined with the generally accepted methods hitherto used in phase-contrast microscopy and in routine histological procedures. It is recommended to use thick, cleared sections, as described in the present study including cutting into thinner sections and additional staining according to conventional histological methods

The technique may prove valuable whenever specific problems are to be solved, for instance, problems involved in a definition of the factors responsible for the acutely developing hearing losses. On the assumption that the vascular anastomoses here described contribute to the preservation of a certain integrity of structures in the internal ear in patients of this category it may be taken into consideration to institute oto-neurosurgical measures by which to counteract the defect. Moreover comparative studies of temporal bones and cerebral structures in patients exposed to several audiological tests seem to be of importance for the establishment of more advanced neuro-otological diagnostics

SUMMARY

In the present monograph, including clinical examinations and studies of the normal anatomy as well as the patho-anatomical features involved, it is attempted to detect the factors responsible for the development of the various types of perceptive hearing loss, in particular those responsible for the development of deafness termed "hearing loss pertaining to age".

The monograph comprises two parts:

Part 1. Histological studies of temporal bones and brains from patients with diagnosed hearing loss of perception type (chapters I–V).

Part 2. Experiments including injection of contrast media into the vascular system in temporal bones from man (chapters VI–X).

Chapter I. The material is described and the methods used for dissection of specimens and histological staining of temporal bones and brains are discussed.

Chapter II. The lesions observed in a 43-year-old patient are discussed. His hearing was found to be normal, but a glioblastoma was seen to involve one cerebral hemisphere. Audiometry performed twice during two periods in which cerebral oedema, provoked by the surgical treatment of the tumour, was manifest, revealed on both occasions a symmetrical loss of hearing, applying mainly to tones in the high frequency range; on both occasions, audition paralleled that which, according to the literature, otherwise is seen in normal 75-year-old patients. The last episode of cerebral oedema terminated in the sudden death of the patient. On the basis of histopathological analysis of the brain and of the apparently normal left temporal bone, the following conclusion is drawn: Throughout the periods in which the pathological changes provoked by the tumour involved exclusively the right cerebral hemisphere and the right side of the brain stem, with the exception of the trapezoid body, audition remained normal in this patient while a hearing loss of the presbycusis type occurred during the two episodes of surgically excited cerebral oedema; these episodes were associated with extinct action of the left cerebral hemisphere. In other words, audition is found to fluctuate parallel with pathological lesions involving the cerebrum.

Chapter III comprises a review of previously published works in which the hearing capacity of senile patients is collated with findings obtained by histological studies of isolated parts of the auditory pathways, for instance, single sites in the temporal bone or in the brain.

Some authors have studied the peripheral auditory organ and concluded that pathological lesions at that site were not sufficient to explain the development of the diagnosed hearing loss consequently they suggested that cerebral lesions might be responsible in part, particularly in cases in which the hearing loss applied to tones in the low-frequency range

The attention is directed also to a few reports according to which degeneration of the acoustic nuclei in the brain stem had been demonstrable

Studies are not available however in which the peripheral as well as the cerebral neurones have been examined in patients whose hearing loss developed late in life

Chapter IV The series discussed comprises 1. senile patients who all except one were above the age of 65 years The cerebral auditory pathways, the auditory nuclei in brain stem and cerebral hemispheres, as well as the right and left temporal bones were studied in these patients. In one patient, examination applies only to the right ear

In 11 of the patients, the hearing loss of tones in the high-frequency range is apparently due to cerebral as well as peripheral lesions the loss of hearing of tones in the low-frequency range seems to be attributable exclusively to cerebral lesions since the apical and middle coils remain normal, or only slightly damaged. In one of these 11 patients (the one in group IV) only the right-sided hearing loss could be explained, as mentioned above. In one patient (the one in group III), the loss of hearing of tones in the high-frequency range is explicable exclusively as a consequence of the lesions involving the acoustic nerve and the brain stem since the cochleae on either side remain of normal appearance

Chapter V The past medical history of an 83-year-old patient with Ménière's disease is reviewed. The pathological changes involving the temporal bones and the brain are discussed

The bilateral labyrinthine hydrops can hardly be held solely responsible *for* the hearing loss in particular it cannot be held responsible for her hearing loss applying to tones in the low-frequency range taking into consideration that the labyrinthine hydrops involved mainly the *right* ear on which audition was best preserved Furthermore, the lesions involving the 1st neurone in the acoustic pathways, mostly lesions apically in the cochlea, are not sufficient to explain a loss of hearing of tones in any range on the *other hand*, disappearance and degeneration of cells are by far more marked in the acoustic nuclei and auditory pathways in the brain and hence, the hearing impairment must be considered attributable to cerebral as well as to peripheral lesions, whether the hearing loss applies to tones in the low or high-frequency range.

In contrast, the impairment of the vestibular function is apparently attributabl exclusively to cerebral lesions since there is a clear-cut discrepancy between the severely reduced caloric reactions in both ears and the normal aspect of the vestibular labyrinth, including the 1st neurone coincident with the extremely severe lesions of the vestibular nuclei and pathways in the brain stem.

SUMMARY

In the present monograph including clinical examinations and studies of the normal anatomy as well as the patho-anatomical features involved it is attempted to detect the factors responsible for the development of the various types of perceptive hearing loss, in particular those responsible for the development of deafness termed "hearing loss pertaining to age"

The monograph comprises two parts

Part 1 Histological studies of temporal bones and brains from patients with diagnosed hearing loss of perception type (chapters I–V)

Part 2 Experiments including injection of contrast media into the vascular system in temporal bones from man (chapters VI–X)

Chapter I The material is described and the methods used for dissection of specimens and histological staining of temporal bones and brains are discussed

Chapter II The lesions observed in a 43 year-old patient are discussed His hearing was found to be normal, but a glioblastoma was seen to involve one cerebral hemisphere Audiometry performed twice during two periods in which cerebral oedema provoked by the surgical treatment of the tumour was manifest, revealed on both occasions a symmetrical loss of hearing, applying mainly to tones in the high frequency range on both occasions audition paralleled that which according to the literature otherwise is seen in normal, 75 year-old patients The last episode of cerebral oedema terminated in the sudden death of the patient. On the basis of histopathological analysis of the brain and of the apparently normal left temporal bone the following conclusion is drawn Throughout the periods in which the pathological changes provoked by the tumour involved exclusively the right cerebral hemisphere and the right side of the brain stem with the exception of the trapezoid body audition remained normal in this patient while a hearing loss of the presbycousis type occurred during the two episodes of surgically excited cerebral oedema these episodes were associated with *extinct action of the left cerebral hemisphere* In other words audition is found to fluctuate parallel with pathological lesions involving the cerebrum

Chapter III comprises a review of previously published works in which the hearing capacity of senile patients is collated with findings obtained by histological studies of isolated parts of the auditory pathways, for instance single sites in the temporal bone or in the brain

which anterio-posteriorly separates the vestibule from the cochlea, including the osseous shelf between the basal and the middle coils and which medio-laterally separates the middle ear promontory from the internal auditory canal.

Throughout this vascular system, and in all layers of the otic capsule, it is possible to follow the unintermittent course of vessels of arteriolar calibre between the intracochlear structures and distant structures such as the promontory of the middle ear and the internal carotid artery in its course through the carotid canal.

Chapter IX The vascular supply to the acoustic nerve is described. It applies to all age groups that the vascular system in the Schwann part of nerves is richer and more regular than that in the glial parts In the internal auditory canal, the transition between the two patterns produced by injections is clear-cut.

Chapter X The subject matter of this chapter is a synoptic conclusion and discussion of the findings described in Parts 1 and 2.

Part 1 By means of the available methods for light microscopy the degenerative lesions of labyrinthine structures in 14 patients with various types of hearing losses, mainly of the presbycousis type, are found to be less marked than those involving cerebral auditory pathways and centres. In fact, in two patients with presbycousis, the peripheral hearing organ is apparently normal. The Schwann part of the acoustic nerve seems to be well-preserved despite the severe arteriosclerotic lesions of vessels passing through the internal auditory canal at extraneural sites conversely degeneration in the glial part of nerves is of a degree similar to that involving the white matter of the cerebral hemispheres. As regards the cochlea, the only pathological changes other than those attributable to autolysis, include disappearance and degeneration of ganglion cells at the site of the basal coil of the spiral ganglion, although it must be admitted that the feature is not proportional to the diagnosed loss of hearing of tones in the high-frequency range

Thus the conclusion must be that the factor or factors responsible for the diagnosed losses of hearing are such lesions as involve central as well as peripheral sites in the auditory system two of the patients in whom hearing curves were of presbycousis type represent the exception to this rule, their hearing losses being attributable to cerebral lesions exclusively

Part 2 The results obtained by experimental injections into vessels of 43 human temporal bones derived from patients in all age groups are submitted in part 2. The purpose of such injections is to provide an explanation of the above mentioned findings in temporal bones from the patients discussed in Part 1

It is demonstrated that the cochlear arteries are not end-arteries, rather they are seen to unite with vessels in the otic capsule, particularly at the site of the basal cochlear coil extending further to structures of the middle ear finally to unite directly with carotid branches. Accordingly the cochlea can be filled also via injections into carotid branches Such anastomoses are demonstrable in temporal bones no matter the age of individuals from whom they are removed, the otic capsule is also found to be well-filled with contrast media, even in specimens derived from old patients with severe, generalized arteriosclerosis The demon-

Chapter VI The composition of the material (discussed in Part 2) is described together with the methods used for removal of specimens, experimental injections, and dissection of the 43 temporal bones derived from patients in all age groups. On the basis of this material it is endeavoured to explain some of the patho-anatomical findings discussed in Part 1

Chapter VII is concerned with the vascular communication between the membraneous labyrinth and its otic capsule also the pattern of filling obtained in certain areas of the cochlear vascular system is described

In all temporal bones in which the contrast media appear at the site of the basal cochlear coil in the modiolar vessels (a total of 31) the media are seen to penetrate directly into the enchondral layer of the otic capsule namely via the osseous shelf separating the basal coil from the middle coil. Arterial as well as venous anastomoses between extra and intra labyrinthine vessels are in evidence. In addition vascular communications traversing the endosteal layer are found to unite the intracochlear vascular network with vessels of the enchondral layer This feature is demonstrable in all cochlear coils Such communication is mediated either via canaliculi of capillary calibres interspersed among the osseous fibrils in the endosteal layer *per se* or via arterioles arising from the radiating arterioles of the vestibular scale Anastomoses of these types are demonstrable in all temporal bones, no matter the age of individuals from whom they are derived In the present series they are encountered in one 5-day-old infant as well as in patients above the age of 90 years The various types of vascular anastomoses can all be filled by injections of contrast media via intra as well as extra-cranial vessels known to supply temporal bones Accordingly *the intralabyrinthine arteries are no end arteries*

The intracochlear vascular supply seems to be most abundant at the site of basilar coil structures, especially at the vascular network surrounding the spiral ganglion. Furthermore, vessels in the basilar membrane seem to be well-filled, irrespective of the severity of the degenerative changes involving the organ of Corti, visualized by staining with osmic acid Vessels uniting the vascular stria with the basilar membrane vessels via Reissner s membrane are also in evidence

Chapter VIII The vascular pattern of the otic capsule reproduced by injections into temporal bones, is described the specimens are the same as those discussed in chapter VII The enchondral layer seems to be especially well-provided with vessels this feature is apparent from the injection pattern in temporal bones from patients in all age groups This layer can be filled through extra as well as intra cranial arteries Injections via both sources in one and the same specimen disclose end to-end anastomoses of arteriolar calibres between these Furthermore such duplicate injections reveal the presence of arterio-venous anastomoses which also are of arteriolar calibres

As regards the osseous regions of the osseous capsule filling is most satisfactory in. (a) the region medially to the subarcuate fossa, mainly supplied from the intracranial vessels via the subarcuate arterial branches (b) the osseous region

RESUMÉ

I det forelagte arbejde er det forsøgt ved hjælp af kliniske undersøgelser og normal anatomiske såvel som pathologisk-anatomiske studier at undersøge årsagerne til forskellige former for perceptionshøretab – specielt det såkaldte »aldersbetingede« høretab.

Arbejdet er inddelt i 2 afsnit.

1. Histologiske studier af tindingeben og hjerner fra patienter med kendte perceptionshøretab (kapitel I–V).

2. Experimentelle kontraststofinjectioner af karsystemet i humane tindingeben (kapitel VI–X).

Kapitel I indeholder en beskrivelse af materialet og af de metoder der er brugt ved udtagning og farvning af det histologiske materiale omfattende tindingeben og hjerne.

Kapitel II En 43-årig patient med normal hørelse er fulgt audiometrisk i 2 perioder hvor hjerneødem optrådte efter operative indgreb mod tumor i begge perioder fandtes symmetriske høretab specielt i højfrekvensområdet, svarende til hørelsen man, ifølge litteraturen, møder hos 75-årige patienter. Patienten døde pludseligt i tilslutning til sidste hjerneødemperiode. Ud fra en histopatologisk analyse af hjerne og af venstre os temporale, der findes normale, konkluderes følgende: I perioderne, hvor de patologiske forandringer forårsaget af tumor begrænser sig til h. cerebrale hemisfære og h. side af hjernestammen bortset fra corpus trapezoideum, er hørelsen normal. Under de to perioder med diffust hjerneødem i forbindelse med operationerne, hvor også venstre hemisfære delvis er sat ud af spillet, har patienten det presbyacusislignende høretab. Det vil sige, at hørelsen fluktuerer med de skiftende patologiske tilstande i storhjernen.

Kapitel III omfatter en summarisk gennemgang af tidligere publicerede arbejder hvor forfatterne sammenholder hørelsen hos senile patienter med de histologiske fund i eet enkelt afsnit af hørebanerne, enten *i os temporale eller i hjernen*.

Enkelte forfattere, der har undersøgt det *perifere* høreorgan konkluderer at de patologiske forandringer her ikke er tilstrækkelige til at *forklare* de fundne høretab hvorfor cerebrale forandringer må have spillet en rolle specielt for lavfrekvenshøretabenes vedkommende.

Desuden refereres et par meddelelser vedrørende undersøgelser af de akustiske kerner i hjernestammen, der fandtes degenererede.

I intet arbejde er såvel perifere som cerebrale neuroner undersøgt hos patienter med høretab opstået i senilet.

strable blood supply via the otic capsule serves to explain the observation of well-preserved cochlear structures of the middle and apical coils in old patients. On the other hand these injections fail to explain why structures of the basal cochlear coil have degenerated taking into consideration that vascular anastomoses, via the otic capsule, to this part of the cochlea are found to be particularly abundant. Injections of contrast media fail to provide an explanation of the degenerative changes to be observed by means of osmic acid staining of the organ of Corti and seen to involve the basal cochlear coil in temporal bones from senile patients with generalized arteriosclerosis. In these cases the contrast media are seen to penetrate even into the vessel of the basilar membrane

RESUMÉ

I det foreliggende arbejde er det forsøgt ved hjælp af kliniske undersøgelser og normal anatomiske såvel som pathologisk-anatomiske studier at undersøge årsagerne til forskellige former for perceptionshøretab – specielt det såkaldte »aldersbetingede« høretab.

Arbejdet er inddelt i 2 afsnit:

1. Histologiske studier af tindingeben og hjerner fra patienter med kendte perceptionshøretab (kapitel I–V).

2. Experimentelle kontraststofinjectioner af karsystemet i humane tindingeben (kapitel VI–X).

Kapitel I indeholder en beskrivelse af materialet og af de metoder, der er brugt ved udtagning og farvning af det histologiske materiale omfattende tindingeben og hjerne.

Kapitel II. En 43-årig patient med normal hørelse er fulgt audiometrisk i 2 perioder, hvor hjerneødem optrådte efter operative indgreb mod tumor. I begge perioder fandtes symmetriske høretab, specielt i højfrekvensområdet, svarende til hørelsen man, ifølge litteraturen, møder hos 75-årige patienter. Patienten døde pludseligt i tilslutning til sidste hjerneødemperiode. Ud fra en histopatologisk analyse af hjerne og af venstre os temporale, der findes normale, konkluderes følgende: I perioderne, hvor de patologiske forandringer forårsaget af tumor begrænser sig til h. cerebrale hemisfære og h. side af hjernestammen bortset fra corpus trapezoideum, er hørelsen normal. Under de to perioder med diffust hjerneødem i forbindelse med operationerne, hvor også venstre hemisfære delvis er sat ud af spillet, har patienten det presbyacusislignende høretab. Det vil sige, at hørelsen fluctuerer med de skiftende patologiske tilstande i storhjernen.

Kapitel III omfatter en summarisk gennemgang af tidligere publicerede arbejder, hvor forfatterne sammenholder hørelsen hos senile patienter med de histologiske fund i eet enkelt afsnit af hørebanerne, enten i os temporale eller i hjernen.

Enkelte forfattere, der har undersøgt det perifere høreorgan, konkluderer, at de patologiske forandringer her ikke er tilstrækkelige til at forklare de fundne høretab, hvorfor cerebrale forandringer må have spillet en rolle, specielt for lavfrekvenshøretabenes vedkommende.

Desuden refereres et par meddelelser vedrørende undersøgelser af de akustiske kerner i hjernestammen, der fandtes degenererede.

I intet arbejde er såvel perifere som cerebrale neuroner undersøgt hos patienter med høretab opstået i senlet.

Kapitel IV Hos 12 senile patienter hvoraf kun een er under 65 år har man undersøgt cerebrale hørebaner og kerner i hjernestammen og hemisfærerne såvel som begge perifere høreorganer I eet tilfælde dog kun højresidige

Hos de 11 patienter (hos 1 patient (gruppe IV) var kun højre øre impliceret) hvis høretab omfattede både *høje og lave toner synes højttonetabet at være cen*tralt såvel som perifert betinget, mens lavtonetabet må være udelukkende centralt betinget idet de apicale og mellemste vindinger er normale eller kun let forandrede. Hos en enkelt patient (I gruppe III) kan høretabet, der er et højttonetab kun forklares som et resultat af *forandringerne i nervi acustici og hjernen idet* cochleae på begge sider er normale

Kapitel V Man gennemgår sygehistorie og patologiske fund i ossa temporalia og hjernen hos en 83 årig patient med morbus Ménièri og arteriosclerose

Den dobbeltsidige hydrops labyrinthii synes ikke at være eneste årsag til patien*tens høretab* specielt ikke til det tab der omfatter lavfrekvensområdet, da den er mest udtalt i grad og udstrækning i højre øre, hvor hørelsen er bedst bevaret. Tillige er de patologiske forandringer i 1 neuron af de akustiske baner ikke tilstrækkelige specielt ikke de i den apicale del af cochlea, til at forklare en høre nedsættelse omfattende noget trin i frekvensområdet derimod er udfald og degeneration langt mere udtalt i de akustiske kerner og -baner i cerebrum Det anses derfor mest sandsynligt, at de akustiske udfaldssymptomer er centralt såvel som perifert betingede hvadenten det gælder lav eller højfrekvensområdet.

De vestibulære udfaldssymptomer synes derimod at være udelukkende centralt betingede, idet der er et åbenbart misforhold mellem den svært nedsatte kaloriske reaktion på begge ører og de tilsyneladende normalt udseende dele af labyrintherne, inclusive 1 neuron *samtidigt med at man ser overordentlig svære forandringer* indenfor de vestibulære kerner og baner i hjernestammen

Kapitel VI omfatter en beskrivelse af materialet og af de metoder der er benyttet ved udtagningen de eksperimentelle karinjektioner samt dissektionen af 43 tindingeben fra mennesker i alle aldersgrupper Ud fra dette materiale har man forsøgt at finde en forklaring på visse af de patologisk-anatomiske forandringer der omtales i afsnit 1

I *Kapitel VII omtales* dels karforbindelserne mellem den membranøse labyrinth og dens otiske kapsel dels fyldningsmønstret i visse områder af cochleas kar

I alle *tindingeben i hvilke kontraststofferne fylder modioluskar svarende* til basale *cochleavinding (ialt 31)* trænger kontrasten direkte ud i den otiske kapsels enchondrale lag via den løst strukturerede knoglehylde, der adskiller basale og mellemste vinding Såvel arterielle som venøse anastomoser *mellem ekstra* og *in*tralabyrinthære kar kan påvises. I alle cochleavindinger findes kar der gennem det endosteale lag, forbinder det intracochleære karnet og den otiske kapsels kar Disse karforbindelser etableres dels via canaliculi af kapillærkaliber mellem selve det endosteale lags knoglefibriller dels via arterioler der udgår fra arteriolae rectae i scala vestibuli Anastomoser af alle de nævnte typer kan demonstreres i tin

tindingeben fra patienter i alle aldersgrupper: de er set hos et 5 dage gammelt barn såvel som hos patienter over 90 år. De kan tillige fyldes ved injektioner i såvel intra- som ekstrakranielle kar, der forsyner tindingebenet. *De intralabyrinthære arterier er således ikke endearterier.*

Intracochleært synes karforsyningen til basale vindings strukturer at være rigelig, specielt i området omkring ganglion spirale cochleae. Endvidere ses god fyldning ud i membrana basilaris, uanset graden af de degenerative forandringer i det Cortiske organ, der kan iagttages ved hjælp af osmiumsyrefarvningerne. Der ses endvidere forbindelseskar mellem stria vascularis og membrana basilaris via membrana Reissneri.

Kapitel VIII. Karinjektionsmønstret i den otiske kapsel beskrives: tindingebensmaterialet er det samme som det, der omtales i kapitel VII. Man ser i tindingeben fra patienter i alle aldersgrupper, at specielt det enchondrale lag er velforsynet med kar. Disse kar kan injiceres fra ekstra- såvel som intrakranielle arterier. Ved injektion fra begge karområder i samme præparat, kan der endvidere demonstreres end-to-end anastomoser af arteriolekaliber mellem disse. Ved sådan dobbeltinjektion findes endvidere arterio-venøse anastomoser af lignende kaliber.

De bedst fyldte knogleregioner er dels dem, der ligger medialt for fossa subarcuata, med tilløb af intrakranielle kar specielt fra a. subarcuata, dels det område, der anteriort-posteriort skiller vestibulum fra cochlea (indefattende knoglebyiden mellem basale og mellemste vinding) samt, medialt-lateralt, canalis auditorius internus fra mellemørets promontorium.

Gennem dette karnet kan man følge kar, der fra intracochleære strukturer udbredt forløber gennem 2 eller 3 lag i den otiske kapsel til, blandt andet, mellemørets strukturer og carotiskar som f.eks. a. carotis interna i dens forløb gennem canalis caroticus.

Kapitel IX. Karforsyningen i nervus acusticus diskuteres. Det gælder for alle aldersgrupper, at karnettet er rigeligere og mere regelmæssigt i nervernes Schwannske del end i deres gliøse afsnit. Overgangen mellem de to injektionsmønstre i canalis auditorius synes skarp.

Kapitel X indeholder en sammenfattende konklusion og diskussion af de i afsnit 1 og 2 omtalte fund.

Afsnit 1. Ved hjælp af de lysmikroskopiske metoder, der har været til rådighed, har man skønnet, at de degenerative forandringer i labyrinthens strukturer er langt mindre udtalte end de forandringer, der er tilstede i hjernens hørebaner og centre hos 14 patienter med perceptionshøretab, specielt høretab af presbyacusistype. Det perifere høreorgan synes endog at være normalt hos to patienter med presbyacusis. Den Schwannske del af *nervi acustici* er tilsyneladende velbevaret til trods for svære arteriosclerotiske forandringer i de kar, der passerer gennem canalis auditorius internus ekstraneuralt, hvorimod nervernes gliøse del ses at være degenereret i samme grad som den hvide substans i de cerebrale hemisfærer. I cochlea er udfald og degeneration af celler i ganglion spirale cochleas basale vinding det

eneste pathologiske fund, der ikke synes at kunne tilskrives postmortelle forandringer omend udfald og degeneration ikke er proportionale med de observerede højttonehøretab

Man må således konkludere, at årsagen, eller årsagerne, til de klinisk fundne høretab skal søges i såvel centrale som perifere afsnit af det auditive system hos to af de her omtalte patienter med presbycusis syntes høretabet dog udelukkende cerebralt betinget.

Afsnit 2 Resultaterne af de eksperimentelle injektioner i kar i 43 tindingeben fra patienter i alle aldersgrupper beskrives med det formål at forklare de perifere læsioner man har observeret hos de i afsnit 1 omtalte patienter Det fremgår at cochleas arterier ikke er endearterier men at de forbinder sig med karrene i den otiske kapsel, specielt rigeligt svarende til basale cochleavinding, og videre ud til mellemørets strukturer samt direkte til carotisgrene Fyldning af cochleae kan således også ske ved injektion af carotisgrene Disse anastomoser kan demonstreres i tindingeben fra patienter i alle aldersgrupper i dette materiale blev også den otiske kapsel velfyldt med kontrast, selv i præparater fra gamle patienter med svær universel *arteriosclerose Den således demonstrerede blodforsyning via den otiske* kapsels kar kan derfor muligvis forklare at man i det kliniske materiale omfattende gamle patienter (afsnit 1) finder velbevarede strukturer i mellemste og apicale cochleavindinger Karinjektionerne forklarer derimod ikke hvorfor specielt basale *cochleavindings strukturer er degenererede idet karanastomoserne*, via den otiske kapsel, til denne del af cochlea findes at være specielt rigelige De degenerative forandringer man, ved osmiumsyrefarvning af det Cortiske organ, har kunnet finde i basale cochleavinding i tindingeben fra senile patienter med universel arteriosclerose, har heller ikke kunnet forklares ved kontrastofinjektionerne idet kontrasten i disse tilfælde har udfyldt endog vas membranae basilaris i tindingeben fra disse

Introduction

Because of its relation to the cricoid cartilage and to the pharyngo-esophageal junction, the cricopharyngeus muscle (CP) has both a laryngeal and pharyngeal function. It acts as an accessory tensor of the vocal cord in singing (Sonninen, 1968 Zenker W and Zenker A. 1960) and in the reflex protective closure of the larynx (Murakami and Kirchner 1971 *a*).

Cricopharyngeal spasm may be caused by an intraluminal foreign body resulting in its being trapped at the esophageal entrance. Some cases of dysphagia have been attributed to cricopharyngeal spasm and "autonomic imbalance Rogers (1935) reported a case of dysphagia cured by bilateral excision of the superior cervical sympathetic ganglion. Some authors have since then proposed that a sympathetic nerve supply to the muscle causes contraction, and the parasympathetic causes relaxation (Sjoberg, 1939 Boferkamp, 1957 *Kirchner 1958*).

Other reports, however reflect doubt on the nerve supply to the CP and even on its type of muscle. In this regard, Lund and Ardran (1964) observed no responses in the CP to stimulation of the vago sympathetic. Levitt et al (1964) concluded, on the basis of EMG studies, that there is no sympathetic motor nerve supply to the CP On the other hand, Kramer et al (1957) reported two cases of CP paresis cured by prostigmine.

Despite these disagreements, and even though its functional components have not been clearly identified, the motor nerve supply to the CP at least in the dog and cat, is generally agreed to be the pharyngo-esophageal or descending pharyngeal nerve (Hwang, 1948).

The precise mechanism of the muscle s sphincteric action has never been clearly described, although it has been studied for over 150 years (Bosma, 1957). It is generally agreed that a zone of increased pressure exists within the CP area at rest, and that this pressure drops only during the act of swallowing (Fyke and Code, 1955). Levitt et al. (1964) concluded that the phasic inspiratory activity which they observed in the CP is controlled by the respiratory center Murakami and Kirchner (1972 *b*) observed motor units in the CP which discharge during inspiration, others which discharge during expiration, and suggested that this combination may explain the muscle s tonic contraction.

In the present study Part I is an electrophysiological investigation of the nerve supply and reflex responses of the CP muscle. Part II is a study of the muscle s responses to various cholinergic and adrenergic agents, as a means of demonstrating its involuntary characteristics and its relation to the autonomic nervous system.

METHODS

Fifty-one adult cats were used in these experiments Light anesthesia was maintained by intraperitoneal injection of 25–30 mg/kg of Nembutal Maintenance doses were given through an intravenous cannula in the basilic vein This cannula was also used for administration of the various drugs under study The CP muscle was exposed by a midline skin incision Low tracheotomy and cannulation were performed.

The sternohyoid and sternothyroid muscles were removed for exposure of the laryngeal nerves Both superior laryngeal nerves (SLN) were cut in order to eliminate artefacts from reflex contraction of the cricothyroid muscles, and to prepare the internal branch of the nerve for electrical stimulation (2 msec. 0.5–1.0 V)

The recurrent laryngeal nerve (RLN) was cut bilaterally to eliminate artefacts due to laryngeal movements, current spread from the internal laryngeal muscles and intraluminal pressure changes resulting from arytenoid movements A pair of recording electrodes supported the central cut end of the left RLN A spiral copper wire recording electrode was placed on the surface of the CP muscle and another on the thyropharyngeus muscle as a control

EMG potentials were displayed on a multichannel oscilloscope (Tektronix 564B) after amplification, monitored by another oscilloscope (Tektronix 561A) through a preamplifier (Tektronix 122). Two audiosystems, then recorded by Grass camera.

Contraction of the CP muscle during electrical stimulation of various nerve fibers was visually observed through a surgical microscope. The degree of contraction was reflected by an intraluminal pressure change which was measured by a closed circuit water filled pressure transducer (Statham P23PC) (Murakami and Kirchner 1971 a)

To maintain the precise location of the pressure transducer within the CP segment, the esophagus was opened the transducer introduced upward into the CP segment and tied into position. Further the left vagus was cut low in the neck to eliminate possible artefacts resulting from descent of the esophagus and the cricoid. The nodose ganglion of the vagus and anterior sympathetic cervical ganglion (ASCG) were prepared for individual stimulation.

Nerve recordings were made from the cricopharyngeal nerve (see Fig. 1) and from two major branches which form the pharyngeal plexus. Potentials in the nerve were amplified by DAM 5 then displayed on these oscilloscopes. Immobilization of the animals by injection of Flaxedil was used to eliminate artefacts from cough, swallowing etc.

RESULTS

1 *Neuroanatomy of the cricopharyngeus muscle*

Maintenance doses were given through an intravenous cannula in the basilic vein. This cannula was also used for administration of the various drugs under study. The CP muscle was exposed by a midline skin incision. Low tracheotomy and cannulation were performed.

The sternohyoid and sternothyroid muscles were removed for exposure of the laryngeal nerves. Both superior laryngeal nerves (SLN) were cut in order to eliminate artefacts from reflex contraction of the cricothyroid muscles, and to prepare the internal branch of the nerve for electrical stimulation (2 msec. 0.5–1.0 V).

The recurrent laryngeal nerve (RLN) was cut bilaterally to eliminate artefacts due to laryngeal movements, current spread from the internal laryngeal muscles and intraluminal pressure changes resulting from arytenoid movements. A pair of recording electrodes supported the central cut end of the left RLN. A spiral copper wire recording electrode was placed on the surface of the CP muscle and another on the thyropharyngeus muscle as a control.

EMG potentials were displayed on a multichannel oscilloscope (Tektronix 564B) after amplification, monitored by another oscilloscope (Tektronix 561A) through a preamplifier (Tektronix 122). Two audiosystems, then recorded by Grass camera.

Contraction of the CP muscle during electrical stimulation of various nerve fibers was visually observed through a surgical microscope. The degree of contraction was reflected by an intraluminal pressure change which was measured by a closed circuit water-filled pressure transducer (Statham P23PC) (Murakami and Kirchner 1971 a).

To maintain the precise location of the pressure transducer within the CP segment, the esophagus was opened, the transducer introduced upward into the CP segment and tied into position. Further, the left vagus was cut low in the neck to eliminate possible artefacts resulting from descent of the esophagus and the cricoid. The nodose ganglion of the vagus and anterior sympathetic cervical ganglion (ASCG) were prepared for individual stimulation.

Nerve recordings were made from the cricopharyngeal nerve (see Fig. 1) and from two major branches which form the pharyngeal plexus. Potentials in the nerve were amplified by DAM-5, then displayed on these oscilloscopes. Immobilization of the animals by injection of Flaxedil was used to eliminate artefacts from cough, swallowing, etc.

RESULTS

1. *Neuroanatomy of the cricopharyngeus muscle*

Contraction of the CP muscle was consistently observed with stimulation of the cricopharyngeal nerve (CPN) but never by the RLN. Large evoked potentials during RLN stimula-

charges in the nerve was almost the same as in the RLN (20–25 msec), while that in the muscle was much longer (45–50 msec) indicating continuing activation of the CP muscle by afferents in the CPN itself (Fig. 2)

This concept is supported by the next experiment. Reflex responses of short latency were frequently recorded from the central cut end of the longer branch by stimulation of that of the shorter branch. This can be termed a pharyngo-pharyngeal reflex and is probably the cause of the cricopharyngeal spasm in the presence of an intraluminal foreign body (Fig 3 A).

Another pathway of the pharyngo-pharyngeal reflex was detected in the glossopharyngeal nerve stimulation of which induced reflex responses in the CPN with a moderate latency. The threshold for this reflex was much higher than for the SLN or the CPN itself (Fig. 3 B)

In a previous study of reflex activation of the laryngeal muscles, laryngospasm was shown to be due to after-discharges occurring mostly in the thyroarytenoid muscle, following cessation of stimulation (Murakami and Kirchner 1972). Similarly with stimulation of the internal branch of the SLN the CP muscle or its nerve displayed the same type of after-discharges. These discharges were of larger voltage than spontaneous tonic discharges, and are most likely the source of cricopharyngeal spasm. For want of a better term, these discharges are referred to as spasmic after-discharges"

With repetitive single shocks (1 per sec) they gradually appeared in increasing number and continued for ten to thirty seconds after cessation of stimulation (Fig. 4). With high frequency stimulation of the internal branch of the SLN discharges in the CP muscle or its nerve appeared at once and continued for some seconds afterward (Fig. 5).

Intraluminal pressure increased with every reflex shock stimulus. The increase was less than that seen in direct stimulation of the CPN. The results indicate that the CPN is composed of several kinds of nerve fibers and that only some of them respond to reflex stimulation. Many other motor fibers including vagal or sympathetic tonic fibers are reflexly inhibited or simply show no reflex response (Fig 6).

Fig 3 Pharyngo-pharyngeal reflexes (A) Responses were evoked in the longer branch of the pharyngeal plexus by single low-voltage stimulation of the shorter branch. This may be responsible for reflex contraction or spasm of the cricopharyngeus in the presence of intraluminal foreign body (B) Strong (3 0 V 0 1 msec) stimulation applied to the glossopharyngeal nerve induced reflex responses in the cricopharyngeal nerve. Note shorter latencies than in the laryngo-pharyngeal reflex in Fig.

After the shorter branch was cut, the CPN was prepared for both stimulating and recording electrodes. Stimulation at various frequencies produced no reflex discharges. This indicates that all of the afferent fibers from the CP muscle reach the vagus trunk from the shorter branch. Afferents in the longer branch then, most likely originate in the thyropharyngeal or hyopharyngeal areas (Fig. 1)

3 *Reflex responses of background activity in the cricopharyngeus muscle*

The CP muscle exhibits a tonic background activity at least under light anesthesia, regardless of the respiratory cycle (Murakami and

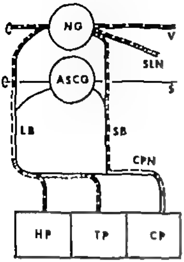

Fig 1 Diagram indicating innervation of the cricopharyngeus muscle Motor neurons, vagal and sympathetic, come through both shorter and longer branches of the pharyngeal plexus, while the afferents pass only through the shorter one Solid and dotted lines indicate efferents and afferents respectively *CP* Cricopharyngeus muscle *TP* thyropharyngeus muscle *HP* hyopharyngeus muscle (middle constrictor) *CPN* cricopharyngeal nerve *SB* shorter branch *LB* longer branch (pharyngo-esophageal nerve), *ASCG* anterior sympathetic cervical ganglion *NG* nodose ganglion *V* vagus nerve *SLN* superior laryngeal nerve

tion before sectioning were clearly shown to be due to current spread from the laryngeal muscles, especially from the posterior cricoarytenoid. Since the CPN was the only nerve that produced consistent responses in the CP muscle an analysis of its functional components was made

Two major branches of the pharyngeal plexus diverge from the vagus nerve the longer branch (the pharyngo-esophageal nerve) leaving the vagus at the cranial end of the nodose ganglion and the shorter branch leaving at the same level as the SLN The longer branch ramifies into small nerves which innervate the hyopharyngeus (middle constrictor) and the thyropharyngeus muscles to form the CPN (Fig 1) The latter nerve shows many turns as it enters the muscle

The central cut end of both the longer and shorter branches showed *spontaneous tonic activity regardless of the respiratory cycle* This tonicity continued even after sectioning the vagus nerve at its entrance into the skull and, in some other cats, after removal of the ASCG The results indicate that both the longer and shorter branches contain efferent nerve fibers of both vagal and sympathetic origin and that some of these efferents possess a spontaneous *tonic activity* at least in light stages of anesthesia

From observations in previous studies the CPN contains afferent fibers which evoke reflex responses in the RLN The RLN responded well to stimulation of the shorter branch in all cases, but only occasionally to stimulation of the longer branch. Most of the afferent fibers therefore are carried by the shorter branch.

2. *Reflex discharges and spasm in the cricopharyngeus muscle*

The CP muscle responded reflexly to stimulation of the internal branch of the SLN Latency was much longer than that in the RLN indicating a greater number of synapses in this reflex pathway The duration of dis-

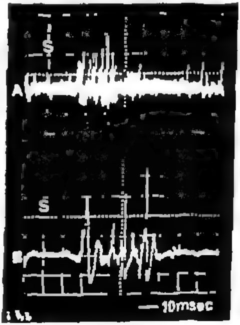

Fig 2 Reflex responses evoked in the cricopharyngeal nerve (A) and in the EMG of the cricopharyngeal muscle (B) by single shock stimulation of the internal branch of the superior laryngeal nerve Note long duration of activity in B, indicating continuing activation of the cricopharyngeal muscle by afferent impulses carried by the cricopharyngeal nerve itself

charges in the nerve was almost the same as in the RLN (20–25 msec), while that in the muscle was much longer (45–50 msec) indicating continuing activation of the CP muscle by afferents in the CPN itself (Fig. 2)

This concept is supported by the next experiment. Reflex responses of short latency were frequently recorded from the central cut end of the longer branch by stimulation of that of the shorter branch. This can be termed a pharyngo-pharyngeal reflex and is probably the cause of the cricopharyngeal spasm in the presence of an intraluminal foreign body (Fig. 3 A).

Another pathway of the pharyngo-pharyngeal reflex was detected in the glossopharyngeal nerve stimulation of which induced reflex responses in the CPN with a moderate latency. The threshold for this reflex was much higher than for the SLN or the CPN itself (Fig. 3 B)

In a previous study of reflex activation of the laryngeal muscles, laryngospasm was shown to be due to after-discharges occurring mostly in the thyroarytenoid muscle following cessation of stimulation (Murakami and Kirchner 1972). Similarly with stimulation of the internal branch of the SLN the CP muscle or its nerve displayed the same type of after-discharges. These discharges were of larger voltage than spontaneous tonic discharges, and are most likely the source of cricopharyngeal spasm. For want of a better term, these discharges are referred to as spasmic after-discharges

With repetitive single shocks (1 per sec) they gradually appeared in increasing number and continued for ten to thirty seconds after cessation of stimulation (Fig. 4). With high frequency stimulation of the internal branch of the SLN discharges in the CP muscle or its nerve appeared at once and continued for some seconds afterward (Fig. 5).

Intraluminal pressure increased with every reflex shock stimulus. The increase was less than that seen in direct stimulation of the CPN. The results indicate that the CPN is

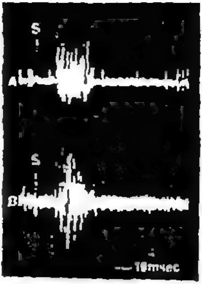

Fig. 3. Pharyngo-pharyngeal reflexes. (A) Responses were evoked in the longer branch of the pharyngeal plexus by single low-voltage stimulation of the shorter branch. Fig 1 Diagram indicating innervation of the cricopharyngeus muscle. Motor neurons, vagal and sympathetic, come through both shorter and longer branches of the pharyngeal plexus, while the afferents pass only through the shorter one Solid and dotted lines indicate efferents and afferents respectively *CP* Cricopharyngeus muscle *TP* thyropharyngeus muscle *HP* hyopharyngeus muscle (middle constrictor) *CPN* cricopharyngeal nerve *SB* shorter branch *LB* longer branch (pharyngo-esophageal nerve) *ASCG* anterior sympathetic cervical ganglion *NG* nodose ganglion *V* vagus nerve *SLN* superior laryngeal nerve

tion before sectioning were clearly shown to be due to current spread from the laryngeal muscles, especially from the posterior cricoarytenoid Since the CPN was the only nerve that produced consistent responses in the CP muscle an analysis of its functional components was made.

Two major branches of the pharyngeal plexus diverge from the vagus nerve, the longer branch (the pharyngo-esophageal nerve) leaving the vagus at the cranial end of the nodose ganglion and the shorter branch leaving at the same level as the SLN The longer branch ramifies into small nerves which innervate the hyopharyngeus (middle constrictor) and the thyropharyngeus muscles to form the CPN (Fig 1) The latter nerve shows many turns as it enters the muscle

The central cut end of both the longer and shorter branches showed spontaneous tonic activity regardless of the respiratory cycle. This tonicity continued even after sectioning the vagus nerve at its entrance into the skull and, in some other cats, after removal of the ASCG The results indicate that both the longer and shorter branches contain efferent nerve fibers of both vagal and sympathetic origin and that some of these efferents possess a spontaneous tonic activity at least in light stages of anesthesia

From observations in previous studies the CPN contains afferent fibers which evoke reflex responses in the RLN The RLN responded well to stimulation of the shorter branch in all cases, but only occasionally to stimulation of the longer branch. Most of the afferent fibers therefore are carried by the shorter branch

2. *Reflex discharges and spasm in the cricopharyngeus muscle*

The CP muscle responded reflexly to stimulation of the internal branch of the SLN Latency was much longer than that in the RLN indicating a greater number of synapses in this reflex pathway The duration of dis

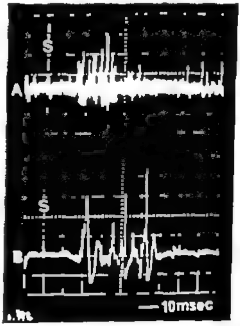

Fig 2 Reflex responses evoked in the cricopharyngeal nerve (A) and in the EMG of the cricopharyngeal muscle (B) by single shock stimulation of the internal branch of the superior laryngeal nerve Note long duration of activity in B indicating continuing activation of the cricopharyngeal muscle by afferent impulses carried by the cricopharyngeal nerve itself

Kirchner 1972 *b*). Many of these discharges originate in the vagus nerve and a few others in the sympathetic, because many of them disappeared after the vagus nerve was sectioned above the nodose ganglion.

With every stimulation of the internal branch of the SLN tonic activity originating in the vagus nerve was briefly inhibited, probably indicating reflex inhibition of the respiratory center. It is probable that this tonic fiber is anatomically different from those which are reflexly activated. This could not be verified because of the difficulty in preparing single nerve fibers of the tonic group.

After the nodose ganglion was removed or damaged, tonic activity was still observed in the CPN although it was very sporadic and low in voltage. This activity is probably mediated through the ASCG. With the nodose ganglion removed, repetitive stimuli applied to the central stump of the vagus produced no detectable reflex discharges in the CPN. However tonic activity in the CPN gradually increased under

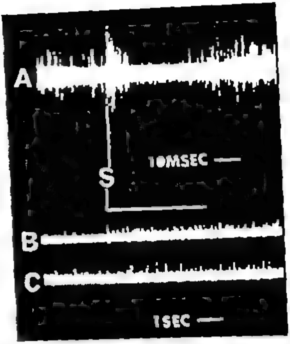

Fig. 7. (A) High-speed recording from the cricopharyngeal nerve after damaging the anterior sympathetic cervical ganglion, showing reflex discharges and inhibition of tonic background activity with single shock stimulation of the internal branch of the superior laryngeal nerve. (B and C) (continuous recording) show that the tonic activity in the cricopharyngeal nerve after removal of the nodose ganglion originates in the anterior sympathetic cervical ganglion. It gradually increases in frequency with repetitive stimulation of the central stump of the vagus.

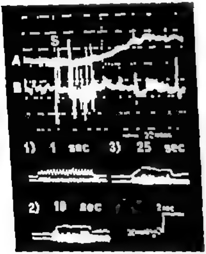

Fig. 6. Increase in intraluminal pressure (upper traces) reflecting reflex contraction of the cricopharyngeal muscle (*EMG* lower traces) with stimulation of the internal branch of the superior laryngeal nerve at different frequencies, 1/sec, 10 sec and 25/sec. Note that the slow pressure increase in the high-speed recording at top and that the degree of increase at the most effective stimulus frequency (25 sec) is not much higher than in single shock or direct stimulation of the motor nerve.

this stimulation. These results indicate that 1) the nerve fibers that discharge reflexly originate in the vagus, and 2) tonic activity in the sympathetic supply to the muscle increases gradually during stimulation of vagal afferents (Fig. 7).

4. *Differences between stimulation of the vagus nerve and of the sympathetic ganglion*

In some animals the vagus nerve was prepared for stimulation up to its entrance into the skull, preserving the nodose ganglion and two major branches which form the pharyngeal plexus and innervate the CP muscle. Direct stimulation at 1.0 to 3.0 volts was delivered to the vagus nerve just above the level of the nodose ganglion. Both directly evoked and

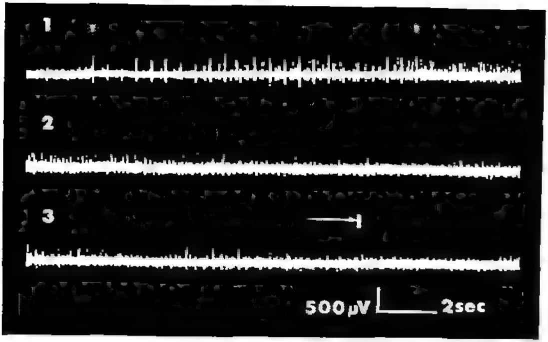

Fig 4 Reflex and after-discharges were evoked in a continuous EMG recording of the cricopharyngeal muscle activity during repetitive single shock stimulation of the internal branch of the superior laryngeal nerve (?/sec, 0.5 V 0.1 msec) between triangular marks in line (1). Small white dots indicate stimuli. Note that spontaneous activity gradually increased and that larger after-discharges lasted for about 30 seconds after cessation of stimulation. Arrow indicates cessation of after-discharges. Duration of after-discharges varied with depth of anesthesia.

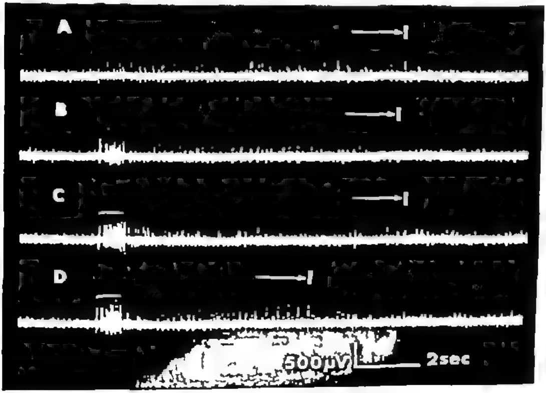

Fig 5 Duration of after-discharges recorded in EMG of the cricopharyngeal muscle by stimulation of the internal branch of the superior laryngeal nerve at different frequencies, 10/sec in A 20/sec in B 30/sec in C and 70 sec in D. Note shorter duration in D indicating that high frequency stimulation not particularly effective. At lower stimulation frequencies, duration of after-discharges is about the same.

Fig 12 Evoked potentials in the cricopharyngeal muscle and intraluminal pressure increase induced by single direct stimulation of both shorter and longer branches of the pharyngeal plexus Note multiphasic potentials and slow pressure increase.

and intraluminal pressure increased. The evoked EMG potential showed a complicated and prolonged wave form, reflecting different conduction velocities among fibers of the various sizes in the CPN (Fig. 12).

The greatest increase in intraluminal pressure with single shock stimulation was 36 mm H_2O at 65–75 msec after activation, reflecting the contraction time of this muscle. Forty-five to fifty msec were required for the pressure to drop to half The half-relaxation time of this muscle is apparently much longer than that of the laryngeal muscles (Murakami and Kirchner 1972 *a*: Mårtensson and Skoglund, 1964 Hast, 1967 *a*, 1967 *b*).

The highest pressure increase (110 mm H_2O) was observed with stimulation at a rather low frequency (20/sec), which is equal to the fusion frequency of the muscle. Tetanus-twitch ratio then is about 3 (Fig. 13)

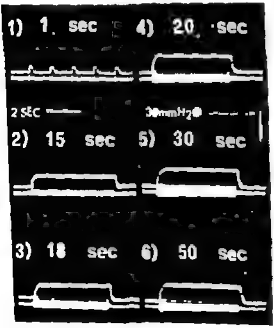

Fig 13 Intraluminal pressure increase (upper traces) reflecting the degree of cricopharyngeal muscle contraction (lower traces) with single or repetitive stimulation of the motor nerve. The highest pressure occurred at relatively low frequency of stimulation (20 sec)

DISCUSSION

The CP muscle is classified as a striated muscle. In contrast to the usual somatic muscle, however its activity is not voluntarily regulated, being inhibited or activated in the course of deglutition as part of a group of muscles systematically controlled by the central nervous system. Moreover the CP exhibits characteristics of slow muscle contracting and relaxing more slowly than the laryngeal muscles (Mårtensson and Skoglund, 1964 Hast, 1967 *a* 1967 *b*) Tetanus-twitch ratio is only 3 indicating a lower innervation-ratio, an arrangement which might be useful for the tonic contraction of a sphincter muscle.

The mechanism of CP spasm in the presence of foreign body is explainable on the basis of these studies. Stimulation of afferent receptors in the pyriform sinus, post-cricoid area or uppermost cervical esophagus evoked reflex contraction and spasm in the CP muscle. Direct stimulation of the mucosa by the tip of the manometer however did not provoke spasm after the SLN had been sectioned. If the SLN is left intact, severe coughing during stimulation by the manometer makes experiments impossible In deeper stages of anesthesia there was no response whatever

In sharp contrast to the CP muscle the thyropharyngeus showed no reflex activation whatever during these experiments.

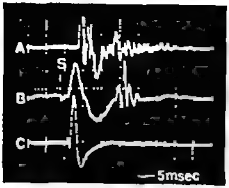

Fig 8 Direct stimulation of the vagus nerve just above the nodose ganglion induced two kinds of discharges, evoked and reflex, in the recurrent laryngeal nerve (A) and in the EMG of the cricopharyngeal muscle (B) By contrast, only an evoked potential was induced in the thyropharyngeal muscle (C)

reflex discharges appeared in the RLN and in the CP muscle In sharp contrast to the CP the thyropharyngeus muscle showed only an evoked potential but never the reflex discharge *(Fig 8) Intraluminal pressure in*creased sharply with each stimulus even after the ASCG was eliminated (Fig 9)

Direct stimulation of the ASCG induced evoked potentials in the CP muscle but never in the thyropharyngeus muscle. Latency was about 7 msec, much longer than with vagus stimulation These results indicate that sympathetic fibers supply only the CP portion of *the inferior constrictor and that the conduc*tion velocity of the sympathetic nerve fibers is much slower than that of motor fibers in

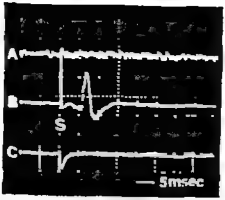

Fig 10 Direct stimulation of the anterior sympathetic cervical ganglion induced evoked potential in the cricopharyngeal muscle (B) but not in the thyropharyngeus (C) or in the recurrent laryngeal nerve (A). The latency in (B) indicates very small diameter fibers (sympathetic) with *slow conduction velocity* By comparison, Fig. 8 (B) shows a very short latency with stimulation of the vagus indicating large diameter fibers.

the vagus (Fig 10) Contraction of the CP muscle *and increase in intraluminal pressure* were observed during ASCG stimulation (Fig 11)

5 Contraction properties of the Cricopharyngeus muscle

After small branches which innervate the thyropharyngeus and the hyopharyngeus muscles had been sectioned both the longer and *the shorter branches of the pharyngeal plexus* were placed on the stimulation electrodes. With every stimulus, the CP muscle contracted

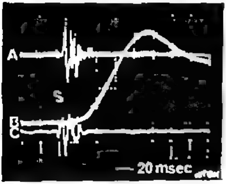

Fig 9 Direct stimulation of the vagus nerve just above the nodose ganglion induced intraluminal pressure *increase* (B) reflected by both evoked and reflex activity in the cricopharyngeus (C). This was true even after removal of the anterior sympathetic cervical ganglion Similar discharges were also evoked *in* the recurrent laryngeal nerve (A)

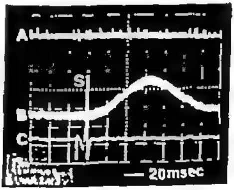

Fig 11 Direct *stimulation of the anterior sympathetic* ganglion induced an evoked potential in the cricopharyngeal muscle (C) but not in the recurrent laryngeal nerve (A) The lower increase in intraluminal pressure recorded at the same gain as in *Fig. 9 (B), indicates a lower number of sympathetic* fibers than vagal

PART II

Neuropharmacological Properties

Hiroyuki Fukuda, M.D. and John A. Kirchner, M.D.

In Part I of the present study two components, vagal and sympathetic, were identified in the innervation of the cricopharyngeus muscle (CP). For a clearer understanding of the involuntary characteristics of the muscle and its relation to the autonomic nervous system the muscle's responses to various adrenergic and cholinergic agents were studied and are here reported as Part II.

Adrenergic effects were studied with the following agents:

1) methoxamine (Vasoxyl®) an alpha stimulator
2) phentolamine (Regitine®) an alpha blocker
3) isoproterenol (Isuprel®) a beta stimulator
4) propanolol (Inderal®) a beta blocker
5) imipramine (Tofranil®) an anti-depressant which decreases re-uptake of norepinephrine at adrenergic nerve endings.

Cholinergic effects were studied with the following:

1) neostigmine (Prostigmine®), an anti-cholinesterase,
2) atropine, a muscarine blocker
3) gallamine (Flaxedil®) a nicotine blocker

The dose level for each drug was arrived at by using, first, the recommended dose per unit weight, then adding more drug until an effect was obtained. This usually proved to be two to three times the recommended dose.

Forty-one cats were used in Part II, five or more for each drug. Recording and stimulating techniques are detailed in Part I of this report.

RESULTS

1 Adrenergic agents

Methoxamine HCL, a predominantly alpha stimulator, was injected intravenously in 10–20 mg amounts. About 30 seconds after administration spontaneous tonic activity appeared in the CP muscle and continued more than 30 minutes if a blocking agent was not given. If an alpha-adrenergic blocking agent was given (phentolamine, 5 mg) this activity became weak or stopped completely within 60 seconds. As a control, the thyropharyngeus showed no tonic activity after administration of methoxamine (Fig. 14).

Propanolol HCL, a beta-blocking agent, had no effect on the activity produced by methoxamine. Similarly a beta-stimulator isoproterenol HCL, produced no discernible activity in the CP.

Stimulation of the internal branch of the superior laryngeal nerve (SLN) at 20 cps or more produced both reflex and after-discharges in the CP. Duration of the after-discharges was longer under light anesthesia than under deep, and longer after methoxamine (Fig. 15).

Imipramine (less than 1 mg/kg) inhibited the activity of the CP which had been induced by methoxamine. This inhibition was complete within 20 seconds after injection of imipramine. Methoxamine-induced activity usually continues for about 30 minutes (Fig. 16).

Similarly tonic activity in the CP was observed with neostigmine, an anti-cholinesterase agent. The activity was not so strong, however as that produced by methoxamine (Fig. 17).

Neuroanatomically the CP is characteristically supplied by sympathetic nerve fibers which discharge tonically giving the muscle a constant tonus as an esophageal sphincter Sympathicotonic influences, then might cause hypertonicity of the CP muscle

Cricopharyngeal spasm in the presence of a pharyngo-esophageal foreign body is probably produced by a combination of spasmic motor discharges of vagal origin and hyper activity of the sympathetic supply

SUMMARY AND CONCLUSIONS

1 The cricopharyngeus muscle is innervated by both vagal and sympathetic components.
2. The cricopharyngeus muscle exhibits a tonic activity which is independent of the respiratory cycle It originates in both the vagal and the sympathetic nerve supplies.
3 The cricopharyngeus muscle contracts reflexly in response to stimulation of laryngopharyngeal afferents (through different pathways from each other).
4 Reflex activation of the cricopharyngeus is followed by after-discharges which may be responsible for spasm This activation is mediated by motor neurons in the vagus nerve
5 Tonic activity of sympathetic origin increases during stimulation of laryngo-pharyngeal afferents.

RESULTS

I Adrenergic agents

Methoxamine HCL, a predominantly alpha-stimulator was injected intravenously in 10–20 mg amounts. About 30 seconds after administration, spontaneous tonic activity appeared in the CP muscle and continued more than 30 minutes if a blocking agent was not given. If an alpha-adrenergic blocking agent was given (phentolamine, 5 mg) this activity became weak or stopped completely within 60 seconds. As a control, the thyropharyngeus showed no tonic activity after administration of methoxamine (Fig. 14)

Propanolol HCL, a beta-blocking agent, had no effect on the activity produced by methoxamine. Similarly a beta-stimulator isoproterenol HCL, produced no discernible activity in the CP

Stimulation of the internal branch of the superior laryngeal nerve (SLN) at 20 cps or more produced both reflex and after-discharges in the CP Duration of the after-discharges was longer under light anesthesia than under deep, and longer after methoxamine (Fig 15).

Imipramine (less than 1 mg/kg) inhibited the activity of the CP which had been induced by methoxamine This inhibition was complete within 20 seconds after injection of imipramine. Methoxamine-induced activity usually continues for about 30 minutes (Fig. 16).

Similarly tonic activity in the CP was observed with neostigmine an anti-cholinesterase agent. The activity was not so strong, however as that produced by methoxamine (Fig. 17).

Neuroanatomically the CP is characteristically supplied by sympathetic nerve fibers which discharge tonically giving the muscle a constant tonus as an esophageal sphincter Sympathicotonic influences, then might cause hypertonicity of the CP muscle

Cricopharyngeal spasm in the presence of a pharyngo-esophageal foreign body is probably produced by a combination of spasmic motor discharges of vagal origin and hyper activity of the sympathetic supply

SUMMARY AND CONCLUSIONS

1 The cricopharyngeus muscle is innervated by both vagal and sympathetic components.

2. The cricopharyngeus muscle exhibits a tonic activity which is independent of the respiratory cycle It originates in both the vagal and the sympathetic nerve supplies.

3 The cricopharyngeus muscle contracts reflexly in response to stimulation of laryngo-pharyngeal afferents (through different pathways from each other)

4 Reflex activation of the cricopharyngeus is followed by after-discharges which may be responsible for spasm This activation is mediated by motor neurons in the vagus nerve

5 Tonic activity of sympathetic origin increases during stimulation of laryngo-pharyngeal afferents.

2. *The effect of adrenergic drugs on reflex activity*

With every single-shock stimulation of the internal branch of the SLN a reflex discharge was observed in the CP and a contraction of the muscle which was proportional to the degree of discharge.

In Fig. 18 the EMG of the CP and of the tongue musculature are displayed during stimulation of the internal branch of the SLN at 0.5 V. The CP shows a very small reflex discharge under normal conditions, but a strong and prolonged response after administration of methoxamine (Fig. 19). By contrast, the reflex response in the tongue muscle, of skeletal type, was not influenced by methoxamine (Figs. 18, 19).

Similarly an alpha-blocking agent, phentolamine, reduced the amplitude and duration of reflex response in the CP but did not affect that in the tongue (Fig. 19).

3. *Effect of cholinergic drugs on reflex activity*

Neostigmine (0.3–0.5 mg) prolonged and accentuated the reflex response in the CP. This effect was inhibited by atropine, a cholinergic blocking agent, but not so dramatically as phentolamine inhibits methoxamine-induced

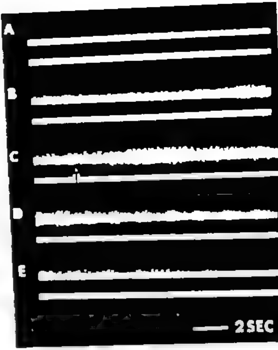

Fig. 16. Inhibition by imipramine of methoxamine-induced activity. Upper traces: EMG of cricopharyngeus. Lower traces: EMG of thyropharyngeus. (A) Before administration of methoxamine. (B) After administration of methoxamine, the activity of the cricopharyngeus muscle gradually increases. (C) After injection of imipramine (arrow) cricopharyngeus activity increases initially for about 5 seconds. (D) The cricopharyngeus activity gradually decreases. (E) Cricopharyngeus activity stops, in this case within 20 seconds after imipramine. A and B, C–E are continuous recordings.

Fig. 17. Effect of adrenergic and cholinergic stimulation on cricopharyngeal tonicity. (A) Methoxamine effect. (B) Neostigmine effect. Each agent was injected about 70 seconds before the beginning of each tracing. The cricopharyngeus was completely silent on EMG before administration of the drug in each case. Both tracings made in the same cat.

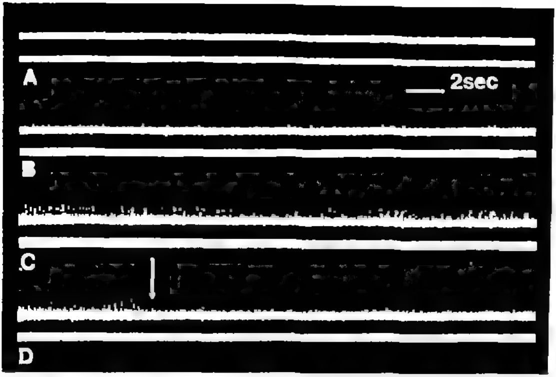

Fig 14 Effect of alpha-adrenergic agents on tonic activity in the cricopharyngeus muscle Upper traces cricopharyngeus muscle. Lower traces thyropharyngeus muscle. (A) Before administration of methoxamine, the cricopharyngeus muscle is completely silent at this level of anesthesia. (B) 30 seconds after administration of methoxamine, an alpha stimulator (C) 70 seconds after administration of methoxamine. (D) Gradual inhibition of tonic activity by phentolamine an alpha blocker Note absence of effect on the thyropharyngeus portion of the inferior constrictor muscle (lower traces)

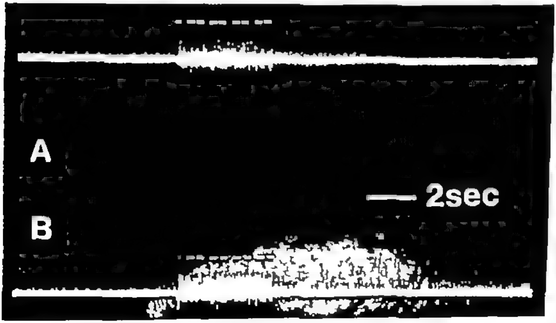

Fig 15 Reflex and after discharges in EMG recordings of the cricopharyngeus muscle by repetitive stimulation of the internal branch *of the superior* laryngeal nerve (30 sec, 0 7 V) (A) Before administration of methoxamine (B) After administration *of methoxamine Note* increased duration of *after discharges*

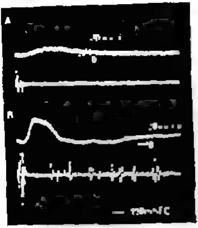

Fig 21 Increase in intraluminal pressure at cricopharyngeus with adrenergic agents (A) Before methoxamine administration peak pressure (top) is less than 25 mm H_2O. (B) After methoxamine administration peak pressure is higher and occurs earlier EMG of cricopharyngeus lower traces Same animal in A and B

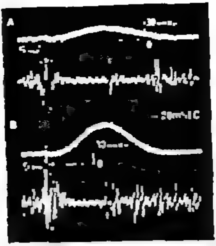

Fig 23 Intraluminal pressure produced by single shock stimulation of the internal branch of the superior laryngeal nerve in control cat (A) Stimulation 1 volt. (B) Stimulation 5 volts. Magnitude of reflex pressure increase is directly proportional to intensity of stimulus, but peak pressure occurs at the same time interval regardless of stimulus strength This is not true after methoxamine, when the peak pressure occurs much earlier after stimulation (compare Fig 21)

sures occurred more quickly and attained levels of 33 mm H_2O and higher (Fig. 21)

With neostigmine, peak pressure was nearly the same as for the control, both in magnitude and in time (Fig. 22)

Magnitude of reflex pressure was directly proportional to the intensity of stimulus delivered to the SLN (Fig. 23). By contrast, the time at which peak pressure occurred after single shock stimulation was always the same, regardless of stimulus strength

In Fig. 24 superimposed pressure curves compare the effects of methoxamine and neostigmine with controls. Methoxamine produces the quickest pressure rises both with single and repeated stimulation.

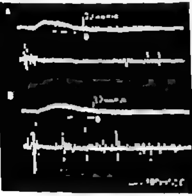

Fig 22 Increase in intraluminal pressure at cricopharyngeus with cholinergic agents Single shock stimulation applied to external branch of the superior laryngeal nerve in the same cat (A) Before neostigmine (B) After neostigmine Resting pressure is higher and peak pressure slightly higher The difference is not so great as with adrenergic agents (see Fig 21)

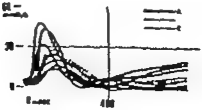

Fig 24 Schema of the curves indicating the onset and degree of pressure increase traced from actual photographs (A) After administration of methoxamine. (B) Normal control. (C) After administration of neostigmine Peak pressure occurs earliest after methoxamine Peak pressure is also higher after neostigmine than in the control, but time of occurrence is nearly the same.

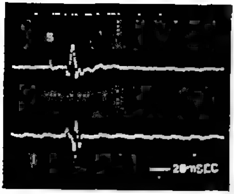

Fig 18 Reflex induced in the cricopharyngeus muscle and in the tongue muscle by single shock stimulation of the internal branch of the superior laryngeal nerve (control for Figs. 19 and 20) Upper trace evoked EMG in cricopharyngeus muscle. Lower trace evoked EMG in tongue muscle.

activity The effect on the reflex response in the tongue muscle was very small (Fig 20)

4 *Effect of neuromuscular blocking agents on reflex response*

Gallamine which competes with acetylcholine at the end-plate receptor in skeletal muscle,

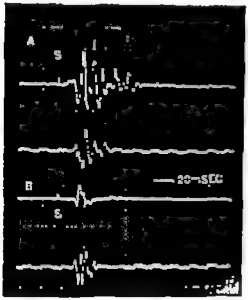

Fig 19 Effect of alpha-adrenergic agents on reflex excitability of cricopharyngeus and of tongue muscle Single shock stimulation applied to internal branch of the superior laryngeal nerve *in the same cat. (A)* After methoxamine administration reflex responses prolonged in cricopharyngeus (upper trace) as compared with tongue (lower trace) and with control in Fig 18 (B) After phentolamine (alpha blocker) had been added *reflex response in* cricopharyngeus (upper trace) returns to normal duration. No change in response of tongue musculature

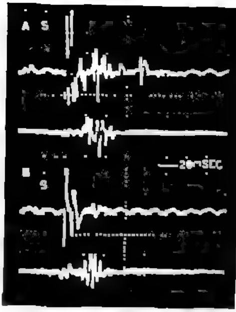

Fig 20 Effect of cholinergic agents on reflex excitability of cricopharyngeus and of tongue muscle. Single shock stimulation applied to internal branch of the superior laryngeal nerve in the sam cat. (A) After neostigmine administration, reflex response is prolonged *in cricopharyngeus (upper trace) as compared* with tongue and with control in Fig. 18 (B) After atropine administration (less than 1 mgm) reflex response in cricopharyngeus (upper trace) returns to normal duration. No change in response of skeletal muscle of tongue.

was used as a neuromuscular blocking agent.

After reflex discharges were recorded in the CP and the tongue muscles to single shock stimulation of the SLN gallamine (0 2 mg or less) was injected intravenously In three cats of the five reflex responses to SLN stimulation ceased simultaneously in both the CP and the tongue muscles. In two other cats, reflex discharges were obtained for a slightly longer time in the CP than in the tongue muscles (25 vs. 20 sec) The difference is probably of no significance.

5 *Intraluminal pressure changes induced by various agents*

Consistent intraluminal pressure increases at the CP occurred with each single shock stimulation of the internal branch of the SLN (1 0 V in all cases.)

Without drugs, peak pressures were less than 25 mm H_2O After methoxamine peak pres-

constrictor muscle and the tongue musculature were not influenced by any of these drugs.

(4) The cholinergic agent affected chiefly the CP muscle

Moreover adrenergic fibers play an excitatory role, whereas cholinergic fibers provide background tonicity since:

(1) Intraluminal pressure increase after electrical stimulation of the internal branch of the SLN was more rapid after injection of the adrenergic agent than of the cholinergic

(2) Spontaneous tonic activity induced by the adrenergic agent was stronger than that produced by the cholinergic.

If then abnormal spasm of the CP is due to autonomic imbalance this imbalance may be within the adrenergic or cholinergic group itself rather than between the two and probably the *former*

DISCUSSION

The site of action of acetylcholine one of the neural mediators, is at the postganglionic para *sympathetic effector organ (muscarinic ac* tion) synaptic transmission in all autonomic ganglia and transmission from motor fiber to skeletal muscle (nicotinic action) It is generally believed that the effect of acetylcholine on smooth muscle is more prominent than that on skeletal muscle. Acetylcholine is destroyed promptly by cholinesterase, so that the effect of acetylcholine can be accentuated by using cholinesterase inhibitors, as for example neostigmine.

A cholinesterase inhibitor has two actions one muscarinic, for excitation of involuntary muscle the other nicotinic, for excitation of skeletal muscle. The former is inhibited by atropine and the latter by curare The muscarinic action of neostigmine is probably produced by cholinesterase inhibition whereas its nicotinic action at least at the neuromuscular site is in part due to a direct effect on the muscle The latter action requires relatively large amounts of neostigmine.

After injection of less than 0.5 mg of neostigmine reflex contraction of the CP muscle to electrical stimulation of the internal branch of the SLN was stronger and continued for a longer time than normally By contrast with skeletal muscle, there was almost no change in the responses of the tongue musculature. Moreover if atropine was administered immediately after the onset of the neostigmine effect reflex responses soon diminished to normal levels. It seems, therefore that the CP reacts physiologically like an involuntary muscle.

In addition the effect of adrenergic drugs on the CP muscle was impressive Under light anesthesia methoxamine injection resulted in spontaneous activity in the CP but not in the thyro-pharyngeus portion of the inferior constrictor In addition this tonic activity was stronger than that produced by neostigmine

The classification of adrenergic receptors as alpha and beta was originally proposed by Ahlquist (1948) In the present experiments, phentolamine, an alpha-blocking agent, consistently inhibited the cricopharyngeal activity induced by methoxamine, an alpha-stimulator Further propanolol a beta blocking agent, did not inhibit this activity Moreover isoproterenol, which stimulates beta receptors, did not excite the CP muscle

It would appear then that the CP is physiologically different from the thyropharyngeus portion of the inferior constrictor and from the striated muscle of the tongue. However in 3 of 5 cats injected with gallamine, reflex excitability in the CP stopped at the same time as that in the tongue musculature. In 2 other cats, reflex excitability lasted only about 3 seconds longer in the CP muscle hardly a significant difference. This would indicate that the CP is not a completely involuntary muscle in all respects. Nevertheless, from observations with blocking and with stimulating agents, it appears that the receptor of the CP muscle is alpha adrenergic, that adrenergic fibers play an excitatory role and that cholinergic fibers furnish background tonicity The two systems, then do not act in opposition

SUMMARY AND CONCLUSIONS

The CP muscle was studied with adrenergic and cholinergic drugs, alpha and beta adrenergic blocking agents cholinergic blocking agents and neuromuscular blocking agents, comparing its activity with that of the thyropharyngeus and the tongue musculature

The CP exhibits characteristics of involuntary muscle with alpha adrenergic receptors, since

(1) Only the alpha-adrenergic drug excited the muscle, and only the alpha-adrenergic blocking agent inhibited this activity

(2) Beta-adrenergic drugs had no effect on its activity

(3) The thyropharyngeal part of the inferior

I Introduction

Modern audiometric methods enable diagnosis of hearing loss due to lesions of the middle ear cochlea or eighth nerve As a rule lesions central to the cochlear nuclei, i.e in the central hearing pathways and auditory cortex are not demonstrable by conventional audiometry The anatomy of the hearing system, with each cochlea represented bilaterally in the auditory cortex, and with several commissural connections at different levels between the pathways of hearing implies a high intrinsic redundancy There is also superfluous information in the ordinary speech message which facilitates complete comprehension by normal subjects But full intelligibility of the message by patients with lesions involving the central hearing system, requires all available information in the speech signals.

Reduction of the information contained in the speech message by various forms of distortions challenges the integrative function of the hearing mechanism and reveals impairment of hearing. This was first shown by Bocca et al (1954 1955) who when testing patients with unilateral temporal lobe disorders used frequency-distorted speech. Using this test method they found a decreased discrimination by the ear on the opposite side of the lesion Several investigators have since used various forms of low-redundant or distorted speech tests and confirmed the original observation by Bocca and his group. (Matzker 1959 Lindén 1960, Jerger 1960 1970 Kimura 1961 de Quiros 1964 Maspétiol et al 1964 Lynn et al 1972 and others).

In a previous study (Korsan-Bengtsen 1968) five different forms of distorted speech tests were standardized and tried on patients with surgically verified lesions of the central hearing system as well as on a group of elderly persons. Preliminary results showed that distorted speech tests were of value in diagnosing lesions in the central hearing pathways and the auditory cortex. The clinical trial revealed that the test material required further improvement. It was also realized that further investigation of the effect of peripheral hearing loss on the test results of distorted speech audiometry was necessary as well as tests on larger series of patients with known anatomical lesions of the CNS. The aim of the present investigation was therefore threefold viz.

1) to devise and standardize a new Swedish normal test material for distorted speech audiometry in different age groups,

2) to evaluate the effect of peripheral hearing loss on the test results of distorted speech audiometry and

3) to analyse the results of distorted speech audiometry in patients with anatomically well-defined lesions in the central nervous system and to correlate the results with the site and extent of the lesions.

AUDIOLOGICAL TERMINOLOGY AND SYMBOLS

Speech reception threshold (SRT) is the sound intensity level at which the listener is capable of correctly repeating 50 percent of standardized Swedish spondee words.

Speech discrimination score is the percentage of correctly repeated words at the optimal speech sensation level – usually 30 dB above SRT

Speech sensation level (SL) is the sound intensity level above the actual SRT

STATISTICS

The statistical methods used in this study are described in "Nonparametric statistics for behavioral sciences" (Sidney Siegel 1956) and Documenta Geigy Wissenschaftliche Tabellen 6 Auflage

Mr Hans Wedel Fil lic. at the Department of Mathematics Chalmers University of Technology was consulted concerning the statistical analyses.

I Introduction

Modern audiometric methods enable diagnosis of hearing loss due to lesions of the middle ear cochlea or eighth nerve As a rule lesions central to the cochlear nuclei, i.e in the central hearing pathways and auditory cortex are not demonstrable by conventional audiometry The anatomy of the hearing system, with each cochlea represented bilaterally in the auditory cortex, and with several commissural connections at different levels between the pathways of hearing implies a high intrinsic redundancy There is also superfluous information in the ordinary speech message which facilitates complete comprehension by normal subjects. But full intelligibility of the message by patients with lesions involving the central hearing system, requires all available information in the speech signals.

Reduction of the information contained in the speech message by various forms of distortions challenges the integrative function of the hearing mechanism and reveals impairment of hearing. This was first shown by Bocca et al (1954 1955) who when testing patients with unilateral temporal lobe disorders used frequency-distorted speech. Using this test method they found a decreased discrimination by the ear on the opposite side of the lesion. Several investigators have since used various forms of low-redundant or distorted speech tests and confirmed the original observation by Bocca and his group. (Matzker 1959 Lindén 1960 Jerger 1960 1970 Kimura 1961 de Quiros 1964 Maspétiol et al 1964 Lynn et al 1972 and others)

In a previous study (Korsan-Bengtsen 1968) five different forms of distorted speech tests were standardized and tried on patients with surgically verified lesions of the central hearing system as well as on a group of elderly persons. Preliminary results showed that distorted speech tests were of value in diagnosing lesions in the central hearing pathways and the auditory cortex. The clinical trial revealed that the test material required further improvement. It was also realized that further investigation of the effect of peripheral hearing loss on the test results of distorted speech audiometry was necessary as well as tests on larger series of patients with known anatomical lesions of the CNS. The aim of the present investigation was therefore threefold viz.

1) to devise and standardize a new Swedish normal test material for distorted speech audiometry in different age groups,

2) to evaluate the *effect of peripheral hearing loss* on the test results of distorted speech audiometry and

3) to analyse the results of distorted speech audiometry in patients with anatomically well-defined lesions in the central nervous system and to correlate the results with the site and extent of the lesions.

II Outlines of the anatomy of the central hearing pathways

It might not be out of place first to give a brief outline of the auditory pathways from the coch lea to the auditory cortex in the temporal lobe (fig. 1) The neuro-anatomic descriptions are taken from the studies by Jungert (1958) Roberts (1960) and Celesia et al (1969).

The cochlear nerve enters the brain stem at the lower border of the pons. It afterwards divides immediately into ascending and descending bran ches which run to the ventral and dorsal cochlear nuclei respectively

After synapsis in the cochlear nuclei the majority of the second order neurons cross over to the contralateral side and relay in the superior olivary complex or dorsal cochlear nucleus or join the lateral lemniscus. Some fibers from the ventral cochlear nucleus join the ipsilateral lemniscus after connections in the medial part of the olivary nucleus. The ascending fibers of the lateral lemniscus thus contain neurons of both the second and the third order and mainly from the contra lateral cochlear nuclei. The ascending acoustic

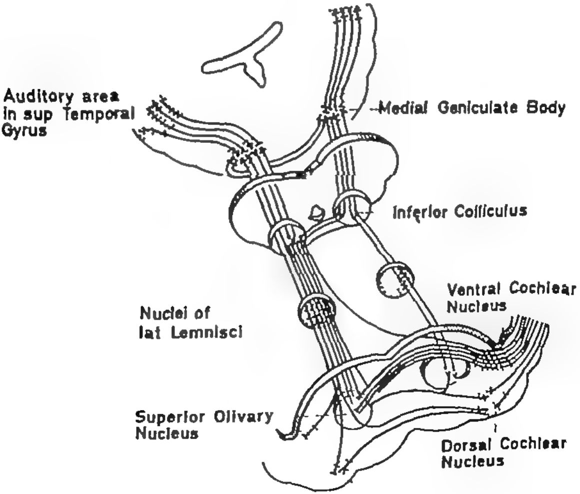

Fig. 1 The central auditory pathways A modification of J ngert s Auditory pathways in the brain stem"

pathway enters the inferior colliculus in the upper part of the brain stem and, after synapses, the fibers run rostrally to the medial geniculate body. There are commissural connections between the two colliculi and probably also between the medial geniculate bodies. The acoustic pathway then forms the so called "auditory radiation" which terminates in the temporal lobe deep in the Sylvian fissure.

Responses in man have been evoked (Celesia 1969) from a small area on the superior surface on the temporal lobe corresponding to the anterior and posterior transverse temporal gyri. This region represents the primary auditory cortex in man, and is schematic illustrated in fig. 2.

In this presentation the term central hearing disorders is used to designate changes in the hearing mechanism caused by lesions in the cochlear nuclei, the ascending hearing pathways and the auditory cortex.

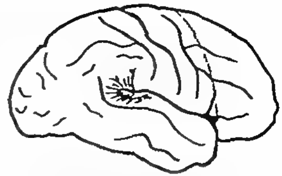

Fig. 2. Outline of auditory cortical area in man, obtained by evoked response (after Celesia and Roberts).

III Speech audiometry in diagnosis of central hearing disorders Survey of the literature

Ordinary speech presents much more information to the listener than is necessary for normal perception Even if some speech sounds should not reach the auditory cortex owing to poor quality of the electroacoustic transmission system or functional impairment of the peripheral hearing organ or of the hearing pathways the remaining speech sounds would still be sufficient for normal discrimination The complicated anatomy of the hearing mechanism with both cochleas bilaterally represented in each auditory cortex and with numerous junctions at different levels of the pathways also contributes to guarantee good speech perception

Owing to this extrinsic and intrinsic redundancy ordinary speech discrimination tests generally fail to reveal local lesions of the auditory cortex or of the central hearing pathways. As early as 1928 Bunch showed that a whisper was heard equally well by a patient who had undergone total rightsided hemispherectomy as by a normal person This holds also for the perception of ordinary speech as has regularly been found in patients with lesions of the central hearing pathways and auditory cortex (Nylén 1939 Bocca et al 1954 1955 1963 Jerger 1960 de Quiros 1964 Korsan Bengtsen 1968 1970b and others)

Bocca et al (1954) were the first to demonstrate that a speech message that was made less redundant by frequency-distortion permitted normal discrimination in normals but a decreased performance by the contralateral ear in patients with unilateral destruction of the auditory cortex This approach to the problem has been used in many investigations which are surveyed below

Speech audiometry tests fall into two main groups monaural and binaural In monaural tests, words, sounds or signals are presented separately to one ear at a time and the recordings made on one side are compared with those obtained on the other In binaural tests both ears are tested simultaneously with equal or different words or signals The result is a summation of the hearing capacity in both ears and will probably be of central origin

MONAURAL SPEECH TESTS

Goldstein Goodman and King (1956) and Goldstein (1961) used a relatively difficult verbal material consisting of indistinctly pronounced PB-words in the examination of 4 patients before and after left-sided hemispherectomy With this (Rush Hughes test) they found a difference of 25% in discrimination between the ipsi and contralateral ear compared with 9% with the ordinary PB-lists. Goetzinger (1972) obtained similar results with Rush Hughes test in patients with central auditory lesions

Frequency-distorted speech

Speech signals can be made low redundant by means of electronic filters which attenuate parts of the frequency spectrum. The discrimination of filtered speech varies considerably with the type of filters used, i.e high pass, low pass or band pass filters as well as with the verbal material

Normal persons can manage fairly large reductions in the frequency spectrum of speech signals before any decrease occurs in the discrimination scores. With a low pass filter with cut-off frequency around 800 Hz or band pass filters with the same rejection of frequencies the intelligibility of sentences is 70–90% at 35–50 dB sensation level (Hirsh 1954 Bocca 1954 1955 Lindén 1960 Maspétiol et al 1964 and Korsan Bengtsen 1968 1970a).

The most important frequencies of speech material such as CVC nonsense syllables and PB-words range from 1500 to 2500 Hz (French and Steinberg 1947 Pollack 1948 and Hirsh 1954)

The use of band pass filters in the low frequency area usually result in somewhat higher discrimination scores than low pass filters within the same frequency range This is because of a masking

effect of the most low frequency sounds in low pass filtered speech (Palva 1965).

Bocca, Calearo and Cassinari (1954) were the first to show that a patient with a right-sided temporal lobe tumour achieved a lower score for filtered speech on the ear opposite to the lesion. Disyllabic meaningful PB-words were used as test material filtered through a low pass filter with a cut-off frequency of 800 Hz. The score for the contralateral ear was reduced by 20–25% compared with that for the ipsilateral ear. In a follow-up study the authors demonstrated the general validity of their original finding by the test results for filtered speech in 111 patients with unilateral temporal lobe disorders. In those cases, where the test results were equal for both ears, surgery confirmed that the tumour had not destroyed the auditory cortex. Bocca and his group thus showed that distorted speech was useful in the exploration of the cortical auditory function.

Bocca (1958) and Calearo and Antonelli (1963) continued their research in filtered speech. Using a low pass filter with a cut-off frequency of 500 Hz they found that the discrimination scores for the contralateral ear in patients with unilateral temporal lobe lesions were reduced by 20–40%. This reduction in perception of filtered speech was the same whether the right or left hemisphere was involved.

Antonelli and Calearo (1968) studied 11 patients with right-sided temporal lobe epilepsy with the filtered speech test before and after surgery. They invariably found a reduced performance with filtered speech whether Heschl's gyrus had been removed or not. They felt that this reduction was due to the disease or surgery with secondary defects in the auditory function in spite of the absence of anatomical changes in auditory cortex, or to the existence of some secondary auditory area enclosing the primary auditory cortex.

Filtered speech tests for diagnosing temporal lobe disorders have thus been widely used (Lindén 1960, Jerger et al 1960, 1964, Maspétiol 1964, Berlin et al 1965, 1972, Korsan-Bengtsen 1968, 1970b and Lynn et al 1972) and the results are in agreement with those reported by Bocca et al.

Using three band pass filters (500 + 640 + 800 Hz) and Swedish spondee words Lindén thus found a decrease in discrimination by nearly 50% on the contralateral ear in 4 patients with temporal lobe tumours. In one case he could not demonstrate any difference between the ears.

Jerger (1964) found a difference of 17% between the ipsi- and contralateral ears in 6 patients with temporal lobe disorders involving Heschl's gyrus. Low pass filtered PB-words (500 Hz) were used as test material. In patients with Mb Parkinson caused by arteriosclerosis or encephalitis Jerger et al (1960) noticed abnormally low scores bilaterally for filtered speech.

The results obtained with filtered speech tests in brain stem lesions vary more than in patients with cortical disease. Calearo and Antonelli (1968) investigated 24 cases with brain stem lesions. 8 had tumours and 16 had lesions due to multiple sclerosis, infections or vascular disorders. Of 23 tested with filtered speech, 8 showed a monolateral deficit, and 4 a bilaterally reduced score. In 7 patients with brain stem lesions Jerger (1964) found a 24% difference in the discrimination score between the homo- and contralateral ear for low pass filtered speech.

Flowers and Costello (1963) investigated low pass filtered speech (960 Hz) in children with speech-articulation deficiencies and found the score to be significantly lower than in normal children. The results suggested that speechretarded children might have changes in the central hearing mechanism.

Many investigations have demonstrated that old people in spite of normal tone and speech audiograms, have reduced perception for filtered speech. Kirikae et al (1964) found that elderly patients had on the average 15% lower discrimination than young subjects, and ascribed this to senile changes in the central hearing pathways and the cochlea. Similar observations have been reported by Korsan-Bengtsen (1968) and Antonelli 1970a).

It is interesting that administration of scopolamine and atropine which have a depressive action on mental performances, markedly reduces the perception of filtered speech in young subjects (Calearo and Antonelli 1964).

Interrupted speech

Speech can be periodically interrupted by an electronic switch, which causes amplitude-modulations of the speech waves (see part IV). In this way parts of the speech message are cancelled. The effect of periodically interrupted speech on discrimination has been investigated in normals by

Similar observations have been reported by Korsan-Bengtsen (1968) and Antonelli 1970a).

It is interesting that administration of scopolamine and atropine which have a depressive action on mental performances, markedly reduces the perception of filtered speech in young subjects (Calearo and Antonelli 1964).

Interrupted speech

Speech can be periodically interrupted by an electronic switch, which causes amplitude-modulations of the speech waves (see part IV). In this way parts of the speech message are cancelled. The effect of periodically interrupted speech on discrimination has been investigated in normals by

among others Miller and Licklider (1950) Bocca 1958 Calearo and Antonelli (1963) and Teatini (1970a). The discrimination was found to depend on the number of interruptions per second (int/sec) as well as the ratio between the duration of the periods of speech and that of the intervals. When the interruption rate is increased from 1 to 10 000 the discrimination score is increased from around 50% to 85% at 10 int/sec. Any further increase in the interruption rate has only little effect on the score Teatini (1970) found some what higher scores at 10 int/sec probably because sentences were used as test material instead of PB-words, which suffer very quickly by various forms of distorsion.

If periodically interrupted speech is presented to patients with unilateral temporal lobe disorders, the discrimination score will be reduced on the side opposite the lesion as shown by Bocca (1958) Calearo and Antonelli (1963) and Antonelli (1970c). The score is 15–25% lower than that for the ipsilateral ear whether the lesion is right or leftsided. This reduced performance with interrupted speech was also evident in patients brain stem lesions, where one or both ears showed a poor discrimination score (Bocca 1963 1967) Calearo and Antonelli (1968)

Similar results in brain stem lesions have been reported by Jerger (1970c) who used varying speech-time fractions with synthetic sentences.

Bocca (1958), Kirikae (1964) and Antonelli (1970a) tested the effect of periodical interruptions of speech on elderly persons with normal hearing for age They found that the discrimination scores were strongly reduced in this group compared with that in young subjects. The difference in perfor mance was ascribed to degenerative changes in the central hearing pathways and auditory cortex.

The effect of drugs on the performance in tests with interrupted speech is noteworthy Calearo and Antonelli (1964) showed that 1 mg of scopolamine markedly depressed the discrimination score in young test subjects, while atropine and barbiturates did not

In difficult tests, as in interrupted speech the discrimination score might vary with the test subject s intelligence Bocca (1967) and Teatini (1970a) were able to demonstrate a correlation between the intelligence quotient (IQ) and the performance of interrupted speech tests the discrimination score varying with IQ

Time-compressed speech

The intelligibility of a verbal material as a function of an increased speech rate has been investigated extensively (Garvey 1953 Calearo and Lazzaroni 1956 Fairbanks et al 1957 de Quiros 1964 and Korsan-Bengtsen 1968 1970a).

The normal speech rate ranges from 110–140 words/minute (wpm) according the habit of the speaker and the language used Speech can easily be speeded by increasing the playback speed of an ordinary tape-recorder and the effect on the speech will be both a change in the rate and a frequency shift of the speech sounds. Using this method Garvey (1953) showed that the intelligibility of spondee words decreased to 65% at an acceleration of 2 0 and this score was reduced to only 10% when the acceleration was increased further to 2.5 Sentences are affected less by time-frequency distorsion and were almost 90% intelligible at a time-compression of 0 67 as shown by Klumpp and Webster (1961) Fairbanks et al. (1957) obtained similar results for connected discourse with varying speech rates.

The speech-rate can also be increased without any change in the frequency spectrum. Such speeded speech can be obtained either by quick reading of the verbal material or by use of a special tape recorder with a group of rotating playback heads. With this special tape recorder the speech rate can be altered from 0 5–2 0 T When the speech rate is in reased the intensity has to be increased in order to maintain the same intelligibility Calearo and Lazzaroni (1957) thus found that at a speed of 350 wpm there was a threshold shift of 10–15 dB in normals. The discrimination curves kept their shape but were displaced to the right Similar results have been obtained by de Quiros (1964) and Korsan-Bengtsen (1968 1970a) in normals.

The effect of time-compressed speech has also been studied in patients with lesions involving the central hearing pathways and auditory cortex Thus, Calearo and Lazzaroni (1957) Bocca (1958) Bocca and Calearo (1963) de Quiros (1964) and Korsan Bengtsen (1968 1970b) found that localized lesions in the auditory cortex significantly reduced the score achieved by the contra lateral ear for time-compressed speech

Patients with diffuse CNS lesions including those with associated increased intra-cranial pressure generally show a bilateral decrease in

discrimination of time-compressed speech.

Calearo and Antonelli (1968) also studied the effect of time-compressed speech in patients with brain stem lesions and found a decrease in discrimination in 14 out of 23 cases. The loss was mainly unilateral. By administration of barbiturates to young subjects, Antonelli and Calearo (1968) found a significant decrease in perception of time-compressed speech, probably as a result of depression of the reticular formation in the brain stem. Drugs such as scopolamine and atropine had no such effect on the results of the test.

Aged people sometimes achieve a reduced score for time-compressed speech (de Quiros 1964, Korsan-Bengtsen 1968, Antonelli 1970a and Schon 1970) and the reduced performance has been interpreted as a result of degenerative changes in the CNS. It is interesting to note that administration of amphetamine – like drugs to elderly patients significantly improves discrimination of time-compressed speech (Blondam and Bocca 1959).

BINAURAL SPEECH TESTS

If normal speech is presented to both ears simultaneously (di-otic hearing) the discrimination score is higher than when it presented to only one ear (monaural listening). Utilizing this binaural gain, Groen and Hellema (1960) investigated monaural and binaural speech perception in hard-of hearing children. They found that in the presence of peripheral lesions the curve for binaural articulation was much steeper than that for monaural articulation and that the gain in SRT was 9 dB. In children with central deafness the difference between binaural and monaural discrimination did not vary much. This shows that an intact central auditory function is necessary for securing binaural summation of the speech.

If the speech material is made more refined and difficult it is possible to devise more specific tests for central hearing disorders. Bocca (1955) presented speech at a very low intensity to one ear and the same speech, sufficiently intense but low pass filtered, to the other ear. The monaural discrimination did not exceed 50% in either ear. When this speech was delivered simultaneously to the ears, Bocca found that the binaural discrimination was approximately equal to the sum of the monaural scores. This test thus provided a summation or integration of two low-redundant messages.

Calearo (1957) used this binaural test in patients with temporal lobe disorders. He found there was no summation if the low-intensity speech was delivered to the ear opposite the lesion. By reversing the presentation of the stimuli, the patients received a satisfactory binaural summation and the test method could thus be used in the diagnosis of central hearing disorders.

Jerger (1960) used the same testing technique in patients with lesions of the auditory cortex. He showed that the discrimination score was decreased for both types of speech when delivered to the contralateral ear. The binaural summation in either combination was a little better than the score for the ipsilateral ear alone.

That the brain can combine or synthetize incomplete speech sounds from the two ears to a meaningful message was first shown by Arnold (cited by Fletcher 1953). He used low pass filtered speech to one ear (cut-off frequency 1000 cps) and the same test words but high pass filtered to the other ear (same cut-off frequency). Monaural discrimination was very low while binaural listening permitted good discrimination.

The same principle with two incomplete messages to test the central synthetic hearing function was also used by Matzker (1959). To one ear he presented low pass filtered speech (narrow band 500–800 cps) and to the other ear the same speech but high pass filtered (narrow band 1815–2500 cps). The speech information from one band alone was too scanty to warrant more than a 25–30% discrimination score. Delivered binaurally to normals there was good integration of the two fractions and they achieved maximum score by this test. Matzker found that the binaural test showed decreased discrimination score in 80% of all patients with brain tumours. Also patients with cerebral atrophy of varying origin, multiple sclerosis and skull injuries showed an increased number of errors in this test, as also in brain stem lesions. The study of Hall (1965) supports this finding in brain stem lesions, as he found that the middle superior olive participates in two click lateralization. Similar findings with binaural filtered speech in temporal lobe lesions were also made by Tillman, Bocy and Carhart (1966).

The same method, with two incomplete filtered speech material presented to each ear was also

investigated by Lindén (1960) The bands used were low pass filter 640" and high pass filter "2000" or "2000x2" When these bands were tested binaurally Lindén could not show that the binaural discrimination score was inferior to the frequency – distorted monaural speech in patients with an expanding intracranial lesion Similar obser vations are also made by Ohta et al (1967) in the binaural fusion test in patients with brain tumours. Matzker s findings concerning binaural synthesis in central hearing disorders could thus not be proved

Feldman (1964 1967) presented dissimi lar three syllabic words at high intensity levels simultaneously to both ears. Young normal sub jects achieved 100% discrimination score in both ears in this dichotic listening situation. Patients with diffuse central lesions had decreased discrimi nation bilaterally without any difference between the ears. In local lesions of the central hearing pathways perception by the ipsilateral ear was reduced when the brain stem was injuried while patients with lesions above the colliculus inferior achieved only a reduced score for the contralateral ear

A similar type of competitive speech audiometry was used by Kimura (1961a b) Pairs of digits were presented either simultaneously to both ears or alternatively to the right and the left ear In patients who had undergone left or right sided temporal lobectomy she found a significant loss in the contralateral ear on simultaneous presentation to both ears whereas frontal lobectomy had no such effect Damage to the left temporal lobe was found to impair the over-all performance in this test both pre- and postoperatively more than right sided lesions. These results suggest that both auditory cortices take part in discrimination and that the left temporal lobe is particularly impor tant in perception of speech material

Similar results were obtained by Milner (1965) and Oxbury and Oxbury (1969) on patients who underwent temporal lobectomy because of epilep tic seizures.

A similar test method with spondee words in dichotic listening was devised by Katz (1962 1963 1968). The test words were presented in a partially overlapping fashion so that the last part of one spondee word was heard simultaneously with the first part of the following spondee word With this method there was competitive stimulus presented to the ears. Katz showed that patients with lesions in cortical and subcortical areas made an increased number of mistakes by the contralateral ear In peripheral sensorineural hearing loss there was bilateral reduction of the discrimination score By shortening the score achieved with the percentage of errors made in PB-word discrimination it was possible to evaluate the degree of involvement caused by central hearing disorders in these cases. In patients with lesions in the hearing pathways and auditory cortex Jerger (1964) found that the discrimination score for PB-words given by ear phones was reduced when sentences were pre sented simultaneously to the other ear as compe tition Lesions in other parts of the brain had no such effect This test method is thus suitable for exploring disturbances in the central auditory system

Swinging speech

If a verbal material is periodically switched from one ear to the other so that each ear receives half of the message normal subjects will achieve a discrimination score of 90–100% at any switching rate as shown by Bocca (1961 1963) The same results are also obtained in patients with isolated lesions of the auditory cortex (Bocca and Calearo 1963) while in patients with lesions in the brain stem the discrimination curve falls abruptly at a switching rate of 3–8 int/sec. (Calearo and Antonelli 1968) Nine out of 22 patients with brain stem lesions scored low in the swinging speech test while the others achieved a normal score This finding in brain stem lesions is ex plained by a disturbance in the fusion of two separate monaural messages at the level of the crossing of the auditory pathways.

Cherry and Taylor (1954), on the other hand found this "dip" in normals at a switching rate around 4 int/sec. and they attributed this reduc tion in discrimination score to a mental delay due to a switch in attention from one ear to the other At higher interruption rates discrimination was again normal

IV Methodological part

SPEECH MATERIAL USED FOR DISTORTED SPEECH TESTS

The function of auditory cortex is to integrate the incoming sound patterns to a meaningful message to the listener. Speech thus should be the ideal test material in the evaluation of disorders of the central hearing mechanism. For detecting central hearing lesions the speech material should preferably be influenced as little as possible by defects in peripheral hearing. As is well known, the discrimination of short words, such as PB-words, is easily impaired by end organ lesions and still more by nerve fiber deafness (Licklider and Miller 1951, Lidén 1954, Schuknecht 1955, 1958, Walsh and Goodman 1955, Goodman 1957 and others).

The intelligibility of sentences depends on their meaning and the context, and they are thus more resistant to changes in the peripheral hearing mechanism than are words (Jerger 1970b, Teatini 1970b). Sentences also provide a better basis for different forms of distortions than do short words. A disadvantage of sentences is that they can be easily remembered in repeated tests. This can be avoided by using a sufficient number of sentences in each test.

The speech test material which had been used in earlier investigations (Korsan-Bengtsen 1968) for the diagnosis of central hearing disorders had appeared to vary in intelligibility and not to be comprehensive enough.

A new speech test material consisting of 500 sentences was therefore designed. The length of each sentence varied between 4 and 8 words. Difficult and uncommon words were avoided to prevent the influence of intelligence and educational level of the listener.

The test material was recorded on a magnetic tape by a trained male speaker. This speech material, after being recorded, was the master tape. The recording was performed in a sound proof room. A microphone AKG MD 421 and a dual channel Revox A 77 tape recorder were used. The frequency response characteristics of the equipment were checked before recording and was found to be in agreement with the technical data. The new speech test material was then standardized and calibrated on normal hearing subjects to reach the same intelligibility of each sentence. As shown by Harris (1948) the slope of the discrimination curve is much steeper when the intelligibility of the test material is taken into account compared with equal intensity of the test words.

As this new material was intended to be presented at a sensation level of 30–35 dB it was desired to calibrate the sentences so as to produce a discrimination curve with a very steep rise as a function of intensity approaching around 100% discrimination score already at 10–15 dB above the tone threshold. The observation of a subnormal discrimination score should thus not be ascribed to insufficient intensity of the speech, but to other factors of the hearing function of the listener.

Thus, the 500 sentences were tested on 5 young students with normal hearing. The presentation of each sentence started 3 dB below the tone threshold, and the intensity was then increased 1 dB at a time by a special attenuator until the whole sentence was repeated correctly. The mean level was then calculated for each sentence. The mean level of all sentences was 19.8±1.7 dB re 2×10^{-5} N/m^2. The master tape was then replayed, and the level of each sentence was increased or decreased in order to reach the same intelligibility of the test material.

The material of sentences was then divided into 20 lists, each consisting of 25 sentences. As each sentence, independent of its length, contained 4 key words, the maximum discrimination score for each list would thus be 4x25 = 100%. The key words were both mono bi- and polysyllabic.

Lists 9–20 were submitted for periodical interruptions of speech with three different rates of

interruption (see side 16). Lists 1–8 were submitted for time-compression of speech. First, a new recording was made of these 8 lists whereby the speaker accelerated his speech from normally 130 wpm to around 190 wpm without any change in his articulation. This speeded speech was then used for further time-compression (see side 19) by means of a special tape recorder.

The test material also included 4 lists nr 21–24 which were submitted for frequency distorted speech. Each list contained 17 sentences, and the lists had been composed by the Director of the Audiopedic section, Dep. of Audiology, Sodersjukhuset, Stockholm. The recording of these lists had been made earlier by a trained male speaker. A Ferrograph tape recorder and a microphone M 221 A were used after control that their technical performance were in agreement with assigned data.

As an additional test a competing speech test was recorded. SPB-list nr 21 (Lidén 1954) containing 50 phonetically balanced words with a carrier phrase was recorded on one channel and lists nr 9 and 10, together 50 sentences, on the other channel in such a way that each sentence covered both the test word and the carrier phrase. The recording equipment was a Revox A 77 tape recorder and the microphone used was AKG MD 421. A male speaker was used for both recordings in order to avoid differences in voice quality from influencing the discrimination of the test words.

DISTORSIONS INTRODUCED

Periodical interruption of speech

Twelve lists, nr 9–20 of the recorded and adjusted speech material were fed into an electronic interrupter triggered by a Wavetec function generator. In this way the speech signals were periodically interrupted by rectangular amplitude modulations which resulted in a sequence of short speech samples alternating with silent intervals. When the interrupter turned the signal off the intensity of the speech signals was reduced by approximately 80 dB. After having passed the interrupter the distorted speech message was recorded on a Revox A 77 tape recorder. The principal equipment for producing periodically interrupted speech is shown in a block diagram in fig. 3 as is a schematic illustration of the effect on the undistorted speech signals by amplitude modulation.

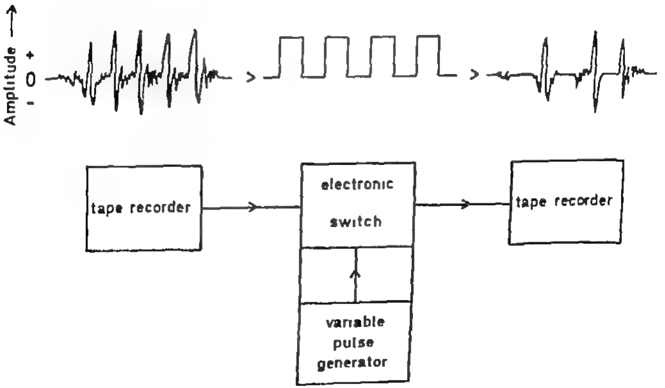

Fig. 3. Block diagram of the eq ipment sed in periodic amplitude modulation of speech

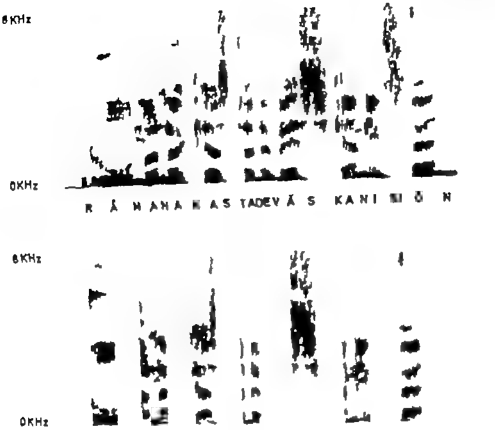

Fig. 4. Sonograms of one of the test sentences before and after amplitude modulations of the speech.

Three rates of interruptions were used, viz 10 7 and 4 int/sec and with a constant speech-time fraction of 0 5

The lists 9–12, containing 100 sentences, were used for the interruption rate of 4 int/second This rate gave duty time of 125 msec of the speech signal

The lists 13–16 with 100 sentences together were used for the interruption rate 7/second. With this rate the speech message was on for about 70 msec

Finally the lists 17–20 containing 100 sentences, were used for the interruption rate 10/second, and the on-time for the speech signals was 50 msec

The recording of the interrupted speech was stored as a master tape and two copies were made for clinical use

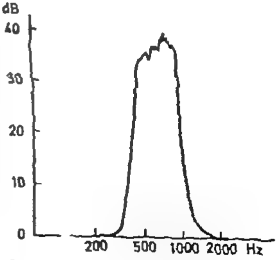

Fig. 5a. Frequency characteristics of 3 band pass filters used, with center frequencies 500 640 800 Hz.

2

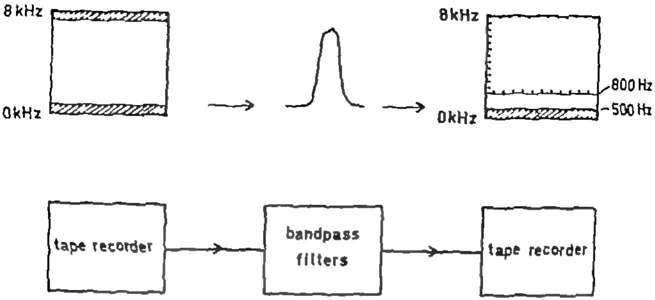

Fig 5b. Schematic illustration of the equipment used in frequency-distortion of speech.

Fig 6. Sonagram of one of the test sentence before nd after frequency-distortion

Sonagrams were made from the original tape and from the same speech material after distortions had been *introduced*. *An illustration is given* in fig. 4.

Frequency – distorted speech

Four lists (nr 21–24) *consisting of all together 68* sentences, were submitted for frequency – distortion of the speech message.

The recorded test material was fed into three band pass filters, coupled in parallel, model Brüel & Kjaer. *Each filter was 1/3* octave wide and center frequencies of the filters were 500 Hz, 640 Hz and 800 Hz, respectively. The attenuation of the coupled filters was 40 dB/octave and the attenuation characteristics of these filters are given in fig. 5a. *After having passed the filters* the frequency – distorted speech lists were recorded on another Revox A 77 tape recorder. Two copies *for clinical use* were made from this master tape. The equipment for frequency – distortion is shown in the block diagram in fig. 5b. As illustration of the effect on speech by band pass filtration, sonagrams were made from the original tape and from the same speech message *after* frequency – distortion (fig. 6).

Time – compression of speech

Eight lists, nr 1–8 were submitted for time compression of the speech. As mentioned earlier the speaker had speeded his speech rate on these lists to around 190 wpm. In order to increase the speed further *the lists were fed into a Tempophon* tape recorder. With this tape recorder the speed of the tape could be changed by means *of* four movable playback heads from 0.5 T to 2.0 T without any change in the frequency spectrum.

The time-compression of the lists were carried out at the Royal Institute of Technology, Stockholm. The lists 1–4, all together *100 sentences*, were submitted for the fastest speed, giving a speech rate of around 290 wpm, corresponding to

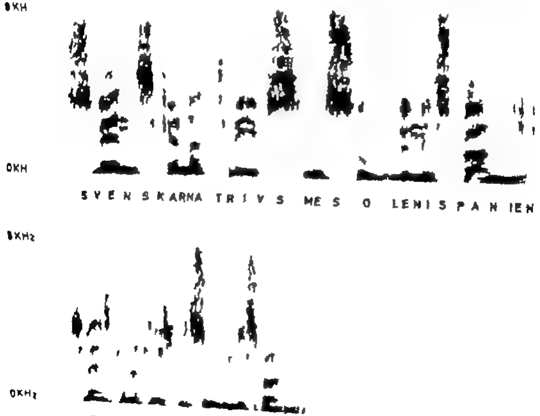

Fig. 7. Sonagrams of one of the test sentences before and after time-compression

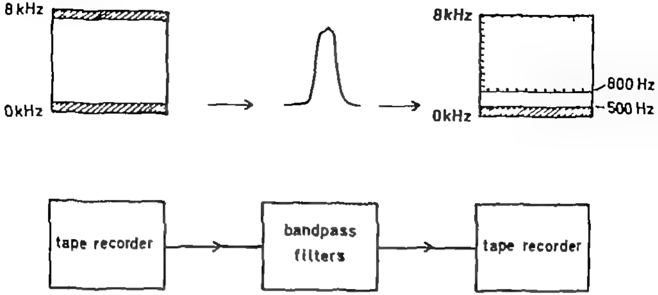

Fig. 5b. Schematic illustration of the equipment used in frequency-distortion of speech

Fig. 6. Sonagrams of one of the test sentences before and after frequency-distortion

materials and were asked to repeat each sentence as correctly as possible. Between each test round, which lasted about 30 minutes, there was a short pause to avoid inattention due to fatigue.

Test methods

Before the tests were started the pure tone hearing threshold was recorded on each ear. Taped spondee and SPB-words (Lidén 1954) were used for ordinary determinations of the speech reception thresholds and discrimination scores for each test subject.

The distorted speech tests were presented monaurally with exception for the competing speech test which was presented in a dichotic way.

Monaurally presented lists

In *material I* the 4 lists within each test, all together 24 lists, were presented in a consecutive test order. The test subjects were allowed to choose which ear they wished to start with, and after finishing a list, there was a shift over to the other ear. Thus, in each test two lists were always presented to the right ear and two to the left.

The first 5–6 sentences in each list were presented at a sensation level of 35 dB. Thereafter the intensity was decreased stepwise after each fifth sentence until the discrimination score dropped to 0–20%.

In *material II* the test method was changed, so that the 4 test lists within each test all together 24 lists, were presented in a randomized order giving twenty-four combinations of the test sequence. Each test list was also divided into 4 parts, and each part was tested at one of the intensities 0 10 20 and 35 dB sensation level. One exception was frequency – distorted speech where 0 dB sensation level was excluded. The order of the intensity levels was also randomized. Both the test sequence between the lists and the intensity sequence for each list were distributed by envelope technique and remained the same through all tests. No test was started at 0 dB sensation level. As a compensation for these six intensity combinations thus discarded six other randomized combinations were added. Two lists were always presented to the right ear and two to the left ear.

In *material III* only the first two lists in each test were presented, and at a sensation level of 35 dB. The test order between the right and left ear was randomized, as was the test order between the two lists.

The test method in *material IV* was exactly the same as for material III. The different tests were always presented to the test subjects in the same order namely with interrupted speech tests first, then frequency – distorted speech, and as the last test time – compressed speech.

Binaural test

The competing speech test was examined on 15 of the test subjects in material III. The SPB-words were presented at 40 dB sensation level to one ear and the competing sentences to the other ear at a sensation level of 50 dB. The test subjects were instructed to ignore the sentences heard on one side and repeat only the SPB-words heard by the other ear. 25 SPB-words were presented to each ear and the test order between the right and left ear was randomized.

RESULTS

Monaural tests

The discrimination scores were calculated relative to the number of correct repeated key-words in each sentence. The mean discrimination scores and standard deviations were calculated for each test list at different sensation levels, as was the sum mean value and standard deviation for each test.

The results obtained in material I with 45 young test subjects, are given in fig. 8 and 9. As can be seen, the mean scores exceeded 90% in all tests at a sensation level of 35 dB except for the test with 4 int/sec. It is also evident that the first list in the test with 4 int/sec. had a lower score than the three other lists in this test. The same observation, although not so pronounced was found in frequency – distorted speech.

The results obtained in material II where the test sequence of the lists and the intensity of the speech were randomized, are given in fig. ▮ and tables I–VI.

The results for the test lists within each test, irrespective of their test order showed that the mean discrimination scores were fairly close to each other at a sensation level of 35 dB. At lower intensities the deviations of the mean discrimination scores and standard deviations were larger as

T = 0.46. The lists 5–8 containing together 100 sentences, were submitted for a moderate time compression, with a received speech rate of around 220 wpm corresponding to T = 0.58. The speed of the speech was calculated by feeding the original and time-compressed speech into a Brüel/Kjaer logaritmic recorder type 2305. The time for each sentence was measured with 1 decimal. The total time required for each list excluding the pauses between the sentences was then calculated.

In this way the number of words per minute (wpm) and the value of T could be computed. After time-compression two copies of the master tape were made for clinical use. In order to illustrate the effect of time-compression on the speech message sonagrams were made from the original tape and from the same speech material after time-compression (see fig. 7).

STANDARDIZATION OF THE TESTS AND TEST METHODS

The purpose of this section was to elucidate the discrimination scores of the new distorted speech material in normals of different ages. The test battery consisted of seven tests:

1) interrupted speech with 10 int/sec. 4 lists, nr 17–20 were used with 25 sentences in each list.

2) interrupted speech with 7 int/sec. 4 lists, nr 13–16 were used with 25 sentences in each list.

3) interrupted speech with 4 int/sec. 4 lists nr 9–12 were used with 25 sentences in each list.

4) frequency – distorted speech. 4 lists nr 21–24 were used with 17 sentences in each list.

5) time-compressed speech I with a speech rate around 220 wpm. 4 lists, nr 5–8 were used with 25 sentences in each list.

6) time-compressed speech II with a speech rate around 290 wpm. 4 lists, nr 1–4 were used with 25 sentences in each list.

7) competing speech test. 2 lists with 25 SPB words in each list were used. As competing message sentences were presented simultaneously.

At the beginning of each list a tone of 440 Hz was recorded for calibration purposes. The level of the tone was adjusted to –5 dB on the VU-meter which corresponds to a sound pressure level of 22.0 dB re 2×10^{-5} N/m^2.

Equipment

The prerecorded speech materials (see side 16) were presented to the test subjects who were wearing earphones via a dual channel Revox A 77 tape recorder, the output of which fed a Madsen or Camplex speech audiometer. Earphones THD 49 Mx 41 AR were used. All tests were performed in sound proof rooms. A Camplex or Madsen tone audiometer was used for determining the tone threshold. These audiometers as well as the earphones, were calibrated according to ISO-standard (1964).

Test subjects

Four groups of test subjects were chosen for standardizing the 7 new types of test material and to determine the performance – intensity curves for the different tests. The criteria for acceptance as a test subject for taking part in the test were that the tone audiogram did not exceed 5 dB at any of the frequencies 250–2000 Hz on both ears, and that the speech reception threshold for the young test subjects did not exceed 5 dB on either ear.

Material I: 45 subjects: 23 women and 22 men. The mean age was 24±4 years (range 17–32 years).

Material II: Another group consisting of 20 subjects, 9 women and 11 men. The mean age was 24±4 years (range 18–34 years).

Material III: Another group of 20 subjects, 11 women and 9 men. The mean age was 26±3 years (range 19–34).

Material IV: 20 subjects, 12 women and 8 men 50–60 years old (55±3.5 years). The mean tone threshold was 5.1±4.2 dB. The mean hearing loss at 4 kHz was 20±14 dB. The mean speech reception threshold for spondees was 7.1±3.3 dB (a hearing level of 0 dB for spondee words correspond to 22.0 dB re 2×10^{-5} N/m^2.

The reason why material IV was included for standardizing purposes was that some of the patients with central hearing disorders would probably be elderly.

Instructions

As this distorted speech material sounds unfamiliar to the listener all test subjects were thoroughly informed about the type of distorsions in the test

excepted. In very good or very difficult listening conditions, i.e. at the top or the bottom of the performance – intensity curve the differences in discrimination between the test subjects should always be small.

However, when the results were analysed with respect to the test sequence of the lists, i.e. the first, second, third and fourth list tested, the score for the list tested first in frequency – distorted speech was reduced, compared with the other three lists in the test, as seen in table IV. No such differences were found between the lists in the other tests.

In order further to evaluate the disparity in performance between the different lists of frequency – distorted speech, the following calculations were made. The discrimination score at 35 dB sensation level for each of the four lists within the six different test was weighed by multiplying the scores by the factors –2, –1, +1 and +2 respectively, and the values obtained by each test subject were summed. A sum around zero would then indicate that the performances with the four lists were fairly close to each other. A positive value, on the other hand, suggested an effect of practice on the results.

Analysed in this way, the medians of the weighted sums for the test subjects were around zero in all tests, with the exception for frequency – distorted speech, where the median value was +44.4. This positive value thus shows that better scores were obtained for the lists tested last then for the list tested first. The corresponding median value for frequency – distorted speech, analysed

1 first tested list   2 second tested list

given in fig. 9. As can be seen, the performance – intensity curves for both materials largely coincide.

In materials III and IV, consisting of 20 test subjects in each group, the first two lists in each test were presented in randomized order at a sensation level of 35 dB.

The results were analysed with regard to the performance in discrimination of the first 7, 13 and the total number of 25 sentences in each list. In material IV the mean discrimination score was also calculated for the last 12 sentences in each list. The results are given in tables VII and VIII.

The differences in discrimination scores, when 7, 13 or 25 sentences were tested, were minimal in the group of young subjects, as were the standard deviations.

In the "old" group on the other hand the results were consistently lower for the first 7 sentences tested than for the last 1 sentences. This difference was most striking in the test with 10 int/sec.

It is also obvious that the capacity was lower throughout in the "old" group than in the young test group. A comparison of the test results calculated with regard to the test order of the lists, is given in table IX. The Wilcoxon's –Mann – Whitney rank order test was applied to the scores.

Statistically significant differences ($p<0.01$) were found between the two age groups in most of the tests. The exceptions were frequency – distorted speech, and the second list tested in time compressed speech and interrupted speech with 10 int/sec.

The results obtained in materials III and IV were also analysed for differences in performance between the right and left ear. Wilcoxon's matched – pairs signed – rank test was applied to the calculated difference for each participant. The null-hypothesis could not be rejected at a significance level of $p<0.01$, i.e., no demonstrable differences in performance was found between right and left ear in any test in the two age-groups.

Competing speech test

In this binaural test, the discrimination score was obtained by calculating the percentage of correct repeated SPB-words, heard in one ear simultaneously with sentences in the other ear. The mean discrimination score for 15 young test subjects was found to be 99.2% for the right ear and 98.4% for the left.

DISCUSSION OF RESULTS

The results on the different forms of distorted speech tests showed very high discrimination scores at a sensation level of 35 dB and the performance was fairly unaffected until the intensity of the speech was reduced to 10–15 dB sensation level.

A comparison between the results for materials II and III showed, that the scores were constantly higher in material III at 35 dB sensation level. An

according to the test number of the lists was +9 8 Wilcoxon s matched – pairs signed – ranks test was also applied to the weight sums for each test The null – hypothesis could only be rejected at *statistically significant level* ($p<0.01$) *for* frequency – distorted speech i e the test results of frequency – distorted speech were influenced by the effect of practice

In view of these findings the disposition of the test material for frequency – distorted speech was changed in such a way that the list tested first was always used as a practice list presented at 35 dB sensation level Lists 2–4 were pooled and divided into two lists of 25 sentences each (one sentence was removed from the tape) The total means of the discrimination scores in each test at different sensation levels and standard deviations were calculated for materials I and II and the results are

1 = first tested list   2 second tested list

the test subjects had had no practice before the test session.

Time – compressed speech

The effect on discrimination when the speech rate was increased from normally 130 wpm to around 220 and 290 wpm respectively was minimal. The scores for the young test subjects exceeded 95% for the fastest speech rate. Also in the group of old subjects the performance was as high as 93% in this test. The time – compression in this investigation was not so pronounced as in similar tests performed by Bocca and Calearo (1963) de Quiros (1964), and Teatini (1970a). They used a speech rate of 350 wpm, which naturally gave lower scores than those achieved in this study.

Comparison of number of sentences tested

Analyses of the results in material III showed that the differences in discrimination when 7, 13 or 25 sentences were tested were minimal in young test subjects. The significance of this finding was that the number of sentences tested in each test could be reduced, if desired, to 7 and still give reliable results. This is worth knowing when handling young patients with central hearing disorders. The patients often have to undergo several examinations, and it is desirable to reduce the testing time as far as possible without lowering the reliability of the results.

When the results for the "old" test group were analysed with regard to 7, 13 or 25 sentences tested, a minor but clear effect of practice was found in all tests (table VIII). This finding was most obvious in the test with 10 int/sec. In the other tests, this effect of practice was not so pronounced probably because the test with 10 int/sec. was always the one presented first to the listeners.

These findings show that elderly patients must get accustomed to the distorted speech tests, and that 50 sentences, i.e. 2 lists are necessary for each test session if the results are to be reliable.

Comparison between right and left ear performance

The left hemisphere dominance in speech reception mechanism is well known. This holds not only for right handed subjects, but also for the majority of left-handed subjects, as shown by Penfield and Roberts (1959).

It was therefore considered worth while to determine whether there is an asymmetry between the hemispheres in recognition of distorted speech tests. Earlier investigations by Calearo and Antonelli (1963) and Dirks (1964) could not prove any differences between right and left ear performance under monaural listening conditions. The results in this study are in agreement with these findings, both for the young and old group. On the other hand, Broadbent (1954), Kimura (1961 a,b), Dirks (1964), Milner (1965), Katz (1962, 1968) and others found that significantly more words were recognized by the right ear contralateral to the dominant hemisphere under dichotic listening conditions. This implies that during competition between the auditory pathways there is an asymmetry between the sides. They also found that when the test subject had to concentrate on one ear and ignore the message simultaneously given to the other ear, there were no significant differences between the sides. In this study of the performance on competing speech this observation was confirmed, as the discrimination score was the same for both the right ear and the left.

ADJUSTMENT OF THE TEST BATTERY FOR CLINICAL USE

The test battery with 7 *different* forms of distorted speech tests, is fairly extensive and might be difficult to manipulate in *routine* work. As a rule the patients have to undergo not only these special tests, but also several of time-consuming and tiring audiological and vestibular examinations. It is thus desirable to reduce the testing time if possible and this can be done by selectively reducing the number of distorted speech tests used.

Periodically interrupted speech was constructed in three different forms with 10, 7 and 4 int/sec respectively. The test with 10 int/sec. was rather easy to perform because of the short off time (50 msec) of the speech signals. On the other hand the test with 4 int/sec. was *fairly difficult* owing to the long off time of 125 msec. The test with 7 int/sec was of average difficulty and is the best test to start with. If for some reason, this test with 7 int/sec. did not give the diagnostic information,

explanation for this difference can be offered only concerning frequency – distorted speech i e the test subjects in material III were used to listening to the distorted speech before the test session had been started As for the other tests the differences in performance might be explained by the assumption that it is easier to listen to a speech test that is constant in intensity than to a test where the sound pressure levels are continously varied

Interrupted speech

The effect on discrimination when the speech information is reduced by periodical interruption is not very pronounced in young test subjects. In the tests with 10 and 7 int/sec respectively the scores exceeded 95% at 35 dB sensation level Also for the test with 4 int/sec where the off time was 125 msec and thus a fair amount of information was cancelled, the scores were still above 80% These findings are in fairly good agreement with those of Miller and Licklider (1950) Calearo and Antonelli (1963) Korsan Bengtsen (1968) and Teatini (1970a) at least for the higher degrees of interruptions. Minor differences in discrimination scores can undoubtedly be ascribed to differences in the speech material used It is noteworthy that no effect of practice was observed in these young test subjects (see table VII) This is not in agreement with the results of Miller and Licklider who found that practice increased the score by 25–30% compared with listeners without such practice

On the other hand this training effect of practice was observed very clearly in the old group as shown in table VIII The score for the test presented first 10 int/sec was increased by almost 20% from the first 7 sentences tested compared with the last 12 sentences in the second list Similar tendencies, though not so pronounced were also observed for the test with 7 int/sec But a more interesting finding was that the most difficult test the test with 4 int/sec., showed the slightest effect of practice The explanation might be that the test is so difficult that more than two lists are necessary to overcome the difficulties. This extension of the test was however not performed The standard deviations were also very large in this test in the old group owing to wide variations in performance between the test subject.

Compared with the results of Kirikae (1964) and Antonelli (1970a) the performance in this group of elderly subjects was as a whole much better in all tests. In test subjects, 50–70 years old Kirikae found a mean discrimination score of 30% at 5 int/sec. Similar results were also obtained by Antonelli with the most difficult forms of periodical interrupted speech, while the easier test with 10 int/sec gave values close to those in this study

Frequency – distorted speech

Analyses of the results in material II with a randomized order between the test lists clearly showed that the performance on frequency – distorted speech was influenced by practice The other tests did not show this effect The score at a sensation level of 35 dB when practice preceeded the test session was around 95% for the young test group while the mean score without practice was 84% as seen in materials I and II This training effect has not been taken into account in earlier studies

The effect on the discrimination of frequency – distorsion in young normals has been widely investigated by among others Bocca Calearo and Migliavacca (1955) Lindén (1960) Bocca and Calearo (1963) Kirikae (1964) and Teati (1970a).

The results varied depending on the type filters used i.e low pass-or band pass filters, a also the type of speech material presente Usually the scores obtained were around 60–8(at a sensation level of 35 dB and thus much low than in the present investigation

In spite of practice in the group of elderly te subjects the scores were lower than in the you test subjects. The mean scores (table VIII) we slightly below 90% There was also a minor effe of practice that persisted throughout the tests the performance on the first tested 7 sentenc was lower than on the last 12 sentences tested

The scores in this study were much higher tha those reported by Antonelli (1970a) who teste elderly patients with normal hearing He use frequency – bands, which gave roughly the effec of a 500 Hz low pass filter With sentences as tes material the score was only 25% at 35 dI sensation level The differences might be due tc both different filters and higher age in his tes group but also to the reduced performance when

V Clinical part

Evaluation of distorted speech tests in patients with peripheral hearing loss

In some patients with central hearing disorders also peripheral hearing may be impaired. It was therefore decided to check the performance of distorted speech tests in patients with hearing loss due to changes in the middle ear or the cochlea.

Earlier reports on the influence of peripheral hearing disorders on the discrimination of distorted speech tests are not very comprehensive. Katz (1962, 1963), de Quiros (1964) and Korsan-Bengtsen (1970a) thus found that pure conductive hearing loss did not alter the performance of distorted speech tests. In cochlear lesions, on the other hand, they found the scores achieved in these special tests to be abnormally low. Similar effects with the use of time-compressed speech on young patients with sensorineural hearing loss have also been reported by Schon (1970). Using synthetic sentences as test material Jerger (1970b) did not find cochlear disorders to affect the performance of competing and interrupted speech tests. In order further to analyse the effect of peripheral hearing loss on the discrimination of distorted speech tests, the following investigation was carried out.

I. Two lists in each test were presented at a sensation level of 35 dB to 11 patients, all together 14 ears, with a pure conductive hearing loss. Their mean age was 29 years. The cause of the middle ear damage was otosclerosis or chronic otitis. The average tone hearing threshold on the impaired side was 40.9 dB and the mean discrimination score 98.3%.

II. Two lists in each test were presented to 8 patients, all together 15 ears, with congenital sensorineural hearing loss of moderate severity. Their mean age was 25 years. The mean pure tone threshold was 33.0 dB and the mean discrimination score 97.9%. In order to find out whether a cochlear lesion was the cause of the impaired hearing the stapedial reflex threshold was recorded in all ears. The recording technique used was that of Klockhoff (1961), Lidén et al (1970, 1972). The stimuli consisted of tones within the frequency range 250–4000 Hz. A normal reflex threshold was recorded in all ears indicating a cochlear lesion. The cause of the impaired hearing was heredity or birth trauma. All patients had been regularly controlled for many years, and repeated hearing tests did not reveal any progress of the hearing impairment.

III. Two lists in each test were presented to 10 patients, all together 10 ears, with acquired sensorineural hearing loss. The test group was made up of patients with losses due to Ménière's disease, trauma or cochlear otosclerosis. In no case had the hearing impairment existed more than 5 years. The mean age of the patients was 38 years. The average hearing loss for pure tones was 34.6 dB and the mean discrimination score was 93.2%. Measurement of the stapedial reflex threshold revealed a cochlear lesion in all the cases.

RESULTS

The results of distorted speech tests in the three groups with peripheral hearing loss are given in table X. As can be seen the patients with conductive hearing loss manage the special tests almost as good as normal hearing test subjects.

In the two groups with sensorineural loss caused by cochlear lesions, there was a discrepancy between the congenital and acquired group. The scores for the former group, i.e. with congenital hearing loss, were surprisingly high, and in the easiest tests approached the results obtained in the normals. In the group with acquired hearing loss on the other hand, the scores were markedly reduced in all tests, in spite of almost identical hearing loss on the tone audiogram as those with congenital cochlear impairment. Test results in two cases, one with acquired and one with a congenital lesion, are shown in figures 10 and 11.

i e was too easy or too difficult for the patient the test session could be continued with one of the other forms of interrupted speech tests.

The same argument holds also for time compressed speech where it was suitable to start with the highest speech rate i e 290 wpm. When this speed was too difficult for the patient the *lower speech rate of 220 wpm was used*

It is clear from table VII that in young test subjects it was sufficient to test only one list in each test half of it presented to one ear the other half to the other But in elderly test subjects the results showed that it was advisable to test a whole list on each ear if the results were to be reliable

The test were usually presented at a sensation level of 35 dB As the performance – intensity curves were very steep (fig 9) a lower intensity was used when desired Judging from experience with this test battery the best choice of primary tests are those with interrupted speech with 7 *int/sec frequency – distorted speech preceded* by practice time – compressed speech II and competing speech test Using one list in each test it will take about 20–30 minutes to go through a test battery of this design.

V Clinical part

Evaluation of distorted speech tests in patients with peripheral hearing loss

In some patients with central hearing disorders also peripheral hearing may be impaired. It was therefore decided to check the performance of distorted speech tests in patients with hearing loss due to changes in the middle ear or the cochlea.

Earlier reports on the influence of peripheral hearing disorders on the discrimination of distorted speech tests are not very comprehensive. Katz (1962, 1963), de Quiros (1964) and Korsan-Bengtsen (1970a) thus found that pure conductive hearing loss did not alter the performance of distorted speech tests. In cochlear lesions on the other hand they found the scores achieved in these special tests to be abnormally low. Similar effects with the use of time – compressed speech on young patients with sensorineural hearing loss have also been reported by Schon (1970). Using synthetic sentences in test material Jerger (1970b) did not find cochlear disorders to affect the performance of competing and interrupted speech tests. In order further to analyse the effect of peripheral hearing loss on the discrimination of distorted speech tests, the following investigation was carried out.

I Two lists in each test were presented at a sensation level of 35 dB to 11 patients all together 14 ears with pure conductive hearing loss. Their mean age was 29 years. The cause of the middle ear damage was otosclerosis or chronic otitis. The average tone hearing threshold on the impaired side was 40.9 dB and the mean discrimination score 98.3%.

II Two lists in each test were presented to 8 patients all together 15 ears with congenital sensorineural hearing loss of moderate severity. Their mean age was 25 years. The mean pure tone threshold was 33.0 dB, and the mean discrimination score 97.9%. In order to find out whether a cochlear lesion was the cause of the impaired hearing the stapedial reflex threshold was recorded in all ears. The recording technique used was that that of Klockhoff (1961) Lidén et al (1970, 1972). The stimuli consisted of tones within the frequency range 250–4000 Hz. A normal reflex threshold was recorded in all ears indicating a cochlear lesion. The cause of the impaired hearing was heredity or birth trauma. All patients had been regularly controlled for many years, and repeated hearing tests did not reveal any progress of the hearing impairment.

III Two lists in each test were presented to 10 patients all together 10 ears with acquired sensorineural hearing loss. The test group was made up of patients with losses due to Ménière's disease, trauma or cochlear otosclerosis. In no case had the hearing impairment existed more than 5 years. The mean age of the patients was 38 years. The average hearing loss for pure tones was 34.6 dB and the mean discrimination score was 93.2%. Measurement of the stapedial reflex threshold revealed a cochlear lesion in all the cases.

RESULTS

The results of distorted speech tests in the three groups with peripheral hearing loss are given in table X. As can be seen the patients with conductive hearing loss manage the special tests almost as good as normal hearing test subjects.

In the two groups with sensorineural loss, caused by cochlear lesions, there was a discrepancy between the congenital and "acquired" group. The scores for the former group i.e. with congenital hearing loss, were surprisingly high, and in the easiest tests approached the results obtained in the normals. In the group with acquired hearing loss on the other hand the scores were markedly reduced in all tests, in spite of almost identical hearing loss on the tone audiogram as those with congenital cochlear impairment. Test results in two cases, one with acquired and one with a congenital lesion, are shown in figures 10 and 11.

i.e. was too easy or too difficult for the patient the test session could be continued with one of the other forms of interrupted speech tests.

The same argument holds also for time compressed speech where it was suitable to start with the highest speech rate i.e. 290 wpm. When this speed was too difficult for the patient the lower speech rate of 220 wpm was used.

It is clear from table VII that in young test subjects it was sufficient to test only one list in each test half of it presented to one ear the other half to the other. But in elderly test subjects the results showed that it was advisable to test a whole list on each ear if the results were to be reliable.

The test were usually presented at a sensation level of 35 dB. As the performance – intensity curves were very steep (fig. 9) a lower intensity was used when desired. Judging from experience with this test battery the best choice of primary tests are those with interrupted speech with 7 int/sec., frequency – distorted speech preceded by practice time – compressed speech II and competing speech test. Using one list in each test it will take about 20–30 minutes to go through a test battery of this design.

V Clinical part

Evaluation of distorted speech tests in patients with peripheral hearing loss

In some patients with central hearing disorders also peripheral hearing may be impaired. It was therefore decided to check the performance of distorted speech tests in patients with hearing loss due to changes in the middle ear or the cochlea.

Earlier reports on the influence of peripheral hearing disorders on the discrimination of distorted speech tests are not very comprehensive. Katz (1962, 1963), de Quiros (1964) and Korsan-Bengtsen (1970a) thus found that pure conductive hearing loss did not alter the performance of distorted speech tests. In cochlear lesions, on the other hand, they found the scores achieved in these special tests to be abnormally low. Similar effects with the use of time – compressed speech on young patients with sensorineural hearing loss have also been reported by Schon (1970). Using synthetic sentences as test material Jerger (1970b) did not find cochlear disorders to affect the performance of competing and interrupted speech tests. In order further to analyse the effect of peripheral hearing loss on the discrimination of distorted speech tests, the following investigation was carried out.

I. Two lists in each test were presented at a sensation level of 35 dB to 11 patients, all together 14 ears, with a pure conductive hearing loss. Their mean age was 29 years. The cause of the middle ear damage was otosclerosis or chronic otitis. The average tone hearing threshold on the impaired side was 40.9 dB and the mean discrimination score 98.3%.

II. Two lists in each test were presented to 8 patients, all together 15 ears, with congenital sensorineural hearing loss of moderate severity. Their mean age was 25 years. The mean pure tone threshold was 33.0 dB and the mean discrimination score 97.9%. In order to find out whether a cochlear lesion was the cause of the impaired hearing the stapedial reflex threshold was recorded in all ears. The recording technique used was that of Klockhoff (1961), Ladén et al (1970, 1972). The stimuli consisted of tones within the frequency range 250–4000 Hz. A normal reflex threshold was recorded in all ears, indicating a cochlear lesion. The cause of the impaired hearing was heredity or birth trauma. All patients had been regularly controlled for many years, and repeated hearing tests did not reveal any progress of the hearing impairment.

III. Two lists in each test were presented to 10 patients, all together 10 ears, with acquired sensorineural hearing loss. The test group was made up of patients with losses due to Ménière's disease, trauma or cochlear otosclerosis. In no case had the hearing impairment existed more than 5 years. The mean age of the patients was 38 years. The average hearing loss for pure tones was 34.6 dB and the mean discrimination score was 93.2%. Measurement of the stapedial reflex threshold revealed a cochlear lesion in all the cases.

RESULTS

The results of distorted speech tests in the three groups with peripheral hearing loss are given in table X. As can be seen the patients with conductive hearing loss manage the special tests almost as good as normal hearing test subjects.

In the two groups with sensorineural loss, caused by cochlear lesions, there was a discrepancy between the "congenital" and "acquired" group. The scores for the former group, i.e. with congenital hearing loss, were surprisingly high, and in the easiest tests approached the results obtained in the normals. In the group with acquired hearing loss, on the other hand, the scores were markedly reduced in all tests, in spite of almost identical hearing loss on the tone audiogram as those with congenital cochlear impairment. Test results in two cases, one with acquired and one with a congenital lesion, are shown in figures 10 and 11.

i.e was too easy or too difficult for the patient the test session could be continued with one of the other forms of interrupted speech tests.

The same argument holds also for time compressed speech where it was suitable to start with the highest speech rate i.e 290 wpm. When this speed was too difficult for the patient the lower speech rate of 220 wpm was used

It is clear from table VII that in young test subjects it was sufficient to test only one list in each test half of it presented to one ear the other half to the other But in elderly test subjects the results showed that it was advisable to test a whole list on each ear if the results were to be reliable

The test were usually presented at a sensation level of 35 dB As the performance – intensity curves were very steep (fig 9) a lower intensity was used when desired Judging from experience with this test battery the best choice of primary tests are those with interrupted speech with 7 int/sec frequency – distorted speech preceded by practice time – compressed speech II and competing speech test Using one list in each test it will take about 20–30 minutes to go through a test battery of this design.

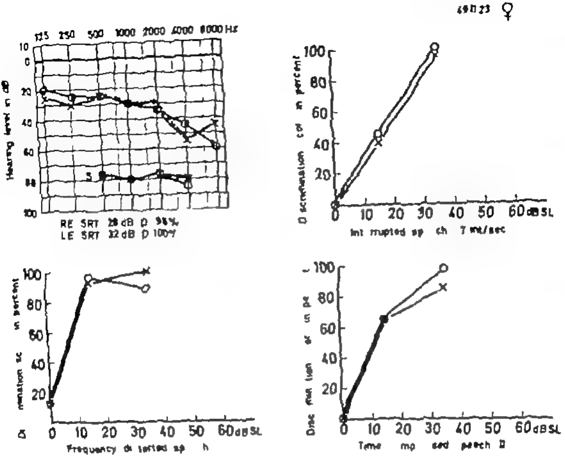

Fig. 11. Test results with ordinary and distorted speech tests in a patient with congenital sensorineural hearing loss.

DISCUSSION OF RESULTS

The performance in the group with conductive hearing loss was that expected. As long as the sound pressure level is raised enough to compensate for the attenuation in the middle ear these patients will manage the distorted speech tests equally well as normals. The performance intensity curves are displaced but retain the same shape as in normals.

The difference in performance between the two groups with cochlear lesions is interesting. The reason why the results in patients with congenital sensorineural hearing loss were so good might be as follows. In these test subjects the central auditory system had been used for analysing speech signals somewhat reduced in redundancy by the cochlear lesion. When the speech signals were made still more low-redundant by means of different forms of distortions, the analytic function of CNS was not stressed more than in normals. In patients with acquired cochlear lesions, on the other hand, the primordial processing of the speech signals is disturbed by the cochlear distortion. When the analytic and interpreting function of the central hearing mechanism is strained still more by addition of distorted speech signals to the ear the discrimination will be notably impaired.

Table X. Mean discrimination scores and standard deviations for distorted and undistorted speech audiometry in young patients with peripheral hearing loss.

Test	Conductive hearing loss (14 ears)	Sensorineural hearing loss congenital (15 ears)	Sensorineural hearing loss acquired (10 ears)
10 int/sec.	96.9±4.6	93.4±7.2	61.2±21.4
7 int/sec	95.8±2.3	89.5±10.9	60.1±20.2
frequency-distorted speech	87.6±15.8	95.9±5.0	46.5±25.8
time-compressed speech II	88.6±12.8	84.3±16.6	51.1±23.0
speech discrimination	98.3±2.6	97.9±4.2	93.2±6.6

Evaluation of distorted speech tests in patients with intra-cranial lesions

As mentioned in part III it is possible to detect disturbances in the central hearing mechanism by speech tests which are made low-redundant by various forms of distorsions In order further to evaluate and classify auditory manifestations accompanying pathological changes in the central nervous system a group of patients with known intra-cranial lesions were tested

MATERIAL

Thirty-three patients aged 10–63 years with intra-cranial lesions were tested In twenty-six the lesion was situated in the temporal lobe either on the right side or on left Of these twenty-three had brain tumours two had intra-cerebral hematomas – one due to trauma one following a ruptured aneurysm Another temporal lesion was epileptogenic. Three patients had tumours in other parts of the hemispheres and four patients had brain stem tumours

All the patients except two had undergone a neurosurgical operation The two patients not explored had a tumour extending from the medulla up to the fourth ventricle in the pons

In order to determine the effect of lesions in various sites on the performance by the patients when tested with distorted speech material the thirty-three patients were classified according to the extent and location of their lesions. This classification was done jointly by a neurosurgeon and a neuroradiologist They judged the anatomical extent of the lesions from the X-ray findings, surgeon s reports, gamma-encephalography EEG visual field defects and other clinical symtoms As a result of their assessments, the patients were divided into four different groups

I – Patients with temporal lobe lesions involving the auditory cortex

Eleven patients five women and six men had a unilateral temporal lobe lesion involving the auditory cortex The patients ages ranged from 14 to 63 years (mean 46) In ten cases the lesion wa[s] situated in the right temporal lobe In one patie[nt] the lesion was left-sided and though it was larg[e] he showed no signs of aphasia. Three patients wer[e] tested a few days before operation the othe[r] cases, *7 days to 6 months after the operatio[n]* Only one case was tested 1 1/2 years after operation and then X-ray examination revealed a *recurrent tumour Representative cases are illustra*ted in figs. 12–16 (the other 6 cases are illustrate[d] in the appendix figs. 31–36)

II a – Patients with temporal lobe lesions not involving the auditory cortex

Nine patients five women and four men ha[d] *unilateral temporal lobe lesions located in th[e] temporal pole distant from the auditory cortex* The patients were 18 to 63 years old (mean 4[0] years) The lesion was right-sided in five and *left-sided in the remaining four None of the* patients had any sign of aphasia Three patients were tested only a few days before the operation *while six were tested post-operatively One* patient with an intra-cerebral hematoma was tested 5 days after the operation and one with a *meningoma 3 months post-operatively The re*maining four patients were tested 6 months – 1 year after the operation One of these patients was *operated upon* because of epilepsy *the others,* because of tumours In none of these patients did X-ray examination or clinical investigation reveal recurrence of the tumour Some cases are illustrated in figs 17–19

II b – Patients with temporal lobe lesions close to the auditory cortex

This group consisted of six patients four women and five men Their ages ranged from 34 to 53 years (mean 4) According to the neurosurgeon and the radiologist the temporal lobe lesions in this group were *situated very close to the auditory* cortex In some cases it was doubtful whether the

tumour had involved deeper structures underneath the cortex, or whether the tumour had displaced the whole temporal lobe and interfered with the function of the auditory cortex. Three of these patients were tested before the operation the other three post-operatively Two of these post operatively tested patients were examined respectively 1 and 2 years after the operation The tests were performed in connection with X-ray examination which had excluded recurrence of the tumour Two representative cases are shown in figs 20–21

III – Patients with intra-cranial tumours in other parts of the hemispheres

This group consisted of only three patients, all with expanding growing tumours One had a frontal lobe tumour on the left side the two a glioma in the parietal lobe one in the right lobe and the other in the left lobe In none of the cases did the tumour involve the auditory cortex or the hearing pathways The patients were tested 10 days 3 months after operation The scores achieved by the patient with a frontal lobe tumour are given in fig 22

IV – Patients with brain stem lesions

This group was made up of four patients Three of them were young, born in 1954–1962 and one a man in 1931 All of them showed multiple neurological signs owing to the infiltrative growth in the pons and adjacent structures Two patients were operated upon one patient received X-ray treatment and the fourth was not explored The diagnosis was made from neurological and X-ray findings The test results of one patient with a brain stem tumour are shown in fig 23

TEST METHODS

The patients with known intra-cranial lesions situated mainly in the temporal lobe were tested during a period of 2 1/2 years During this time the test methods were slightly modified In the earlier test sequences the performance – intensity curves were determined for each test and ear The presentation levels were 0,15 and 35 dB SL, or in most of the cases 15 or 20 35 and 50 dB SL, respectively The ipsilateral ear was always tested first

Later when distorted speech tests were included in the ordinary test battery two lists in each test were presented at 35 dB SL. The test battery was also condensed to comprise the following tests 7 interruptions/sec., frequency – distorted speech, preceded by practice time – compressed speech II and the competing speech test The test with 4 int/sec. was usually too difficult for the patient while the test with 10 int/sec. was often used besides the test with 7 int/sec Ordinary tone and speech audiograms were made on both ears before these special tests were carried out Examination of patients with brain stem lesions included supplementary tests including directional hearing test according to Nordlund (1963), tone decay test stapedial reflex threshold determinations and alternate binaural loudness balance test.

EQUIPMENT

The equipment used for testing these patients with intra-cranial injuries was the same as that described in part IV

In order to enlarge the series of patients with verified temporal lobe lesions, nine additional patients from the Neurosurgical Department Karolinska Hospital, Stockholm and Akademiska Hospital Uppsala, were admitted for tests. The author tested the patients at the Audiological Departments of the respective hospitals

The equipment used in Stockholm was a dual channel Revox A 77 tape recorder which fed a Tegnér SA 4 speech audiometer Earphones THD 39 Mx 41 AR were used. Tegnér T 2 tone audiometer was used for determining the tone thresholds

In Uppsala the same tape recorder was used with a Madsen OB-70 tone and speech audiometer The earphones were THD 49 Mx 41 AR All tests were performed in sound proof rooms.

RESULTS

I – Patients with temporal lobe lesions involving the auditory cortex

The mean values of conventional audiograms were calculated for the eleven cases with unilateral temporal lobe lesions involving auditory cortex. As can be seen from fig. 24 the mean values for the contralateral ears were rather close to the

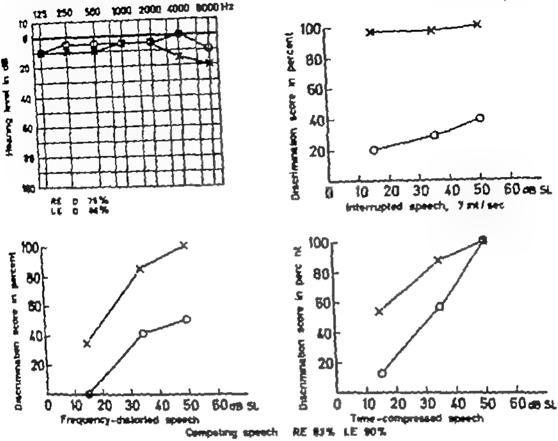

Fig 23 Test results obtained with ordinary and distorted speech audiometry in patient with glioma of the brain stem

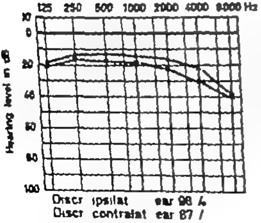

Fig 24 Mean values of the tone- and speech audiograms for the ipsi- and contralateral ears in 11 patients with temporal lobe lesions, involving auditory cortex.

performance of those for the ipsilateral ears, whether it was the right or left ear that was tested In the higher frequency range there was a minor difference between the ears When ordinary speech i e SPB-words were used to determine the discrimination capacity the mean difference between ipsi- and contralateral ears was 11%

The mean scores achieved in the different forms of distorted speech tests are given in fig 25

The test results clearly showed a large difference in performance between the ipsi- and contralateral ear in each test This was most striking in the test with 10 int/sec where the mean difference was nearly 65% at 50 dB sensation level. Also the test with the fastest form of time-compression, i e 290 wpm showed a mean difference of above 50% at 50 dB S L. Frequency – distorted speech on the other hand, showed the smallest difference

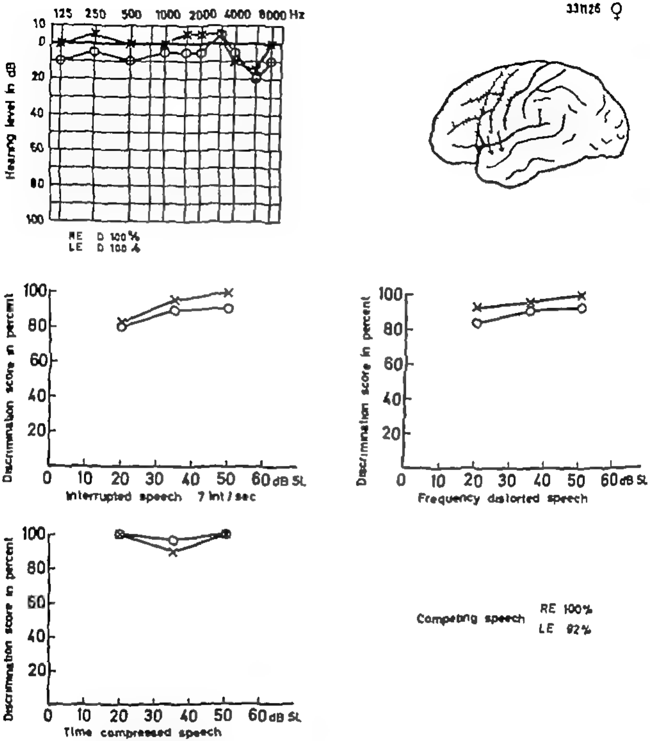

Fig. 22. Test results obtained with ordinary and distorted speech audiometry in patient with a glioblastoma in the left frontal lobe. The tests were performed 3 months after operation.
Dotted area denotes removed tumour.

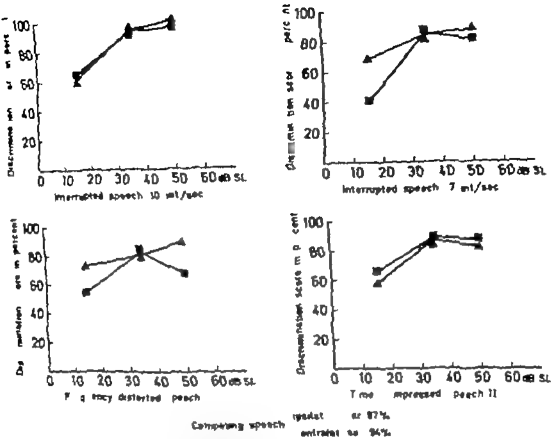

Fig. 27. Mean discrimination scores for the ipsi- and contralateral ears at five different forms of distorted speech audiometry in 9 patients with temporal lobe lesions situated distant from auditory cortex.

performance between the ipsi- and contralateral ears on the tone and speech audiograms. The mean discrimination scores for different forms of distorted speech tests are given in fig. 27. Only very small differences in performance were found between ipsi- and contralateral ears in the test group. All patients were tested at 35 dB SL and at that level the mean scores were almost identical for both ears. Also no roll-over phenomenon was observed in this group compared with group I.

II b. – Patients with temporal lobe lesions, close to auditory cortex

Fig. 28 gives the mean values found at conventional audiometry in six patients with temporal lobe lesions close to the auditory cortex. Both ordinary tone- and speech audiograms

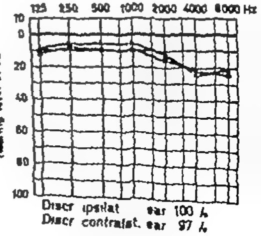

Fig. 28. Mean values of the tone- and speech audiograms in 6 patients with temporal lobe lesions, situated close to auditory cortex.

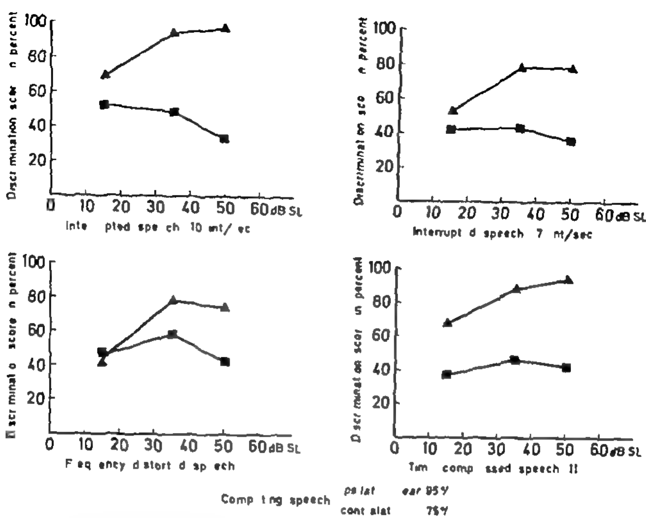

Fig 25 Mean discrimination scores for the ipsi- and contralateral ears at five different forms of distorted speech audiometry in 11 patients with lesions involving auditory cortex.

with only 32% at 50 dB S L between the ipsi and contralateral ear and at 35 dB S L the mean difference was 20%

The roll-over phenomenon which was found in all tests was interesting but most striking in the test with 10 int/sec and frequency – distorted speech *This roll-over effect has been described by* Jerger (1970a) and implies that the performance of the contralateral ear decreases at higher intensity levels more than does that of normal ears

II a – Patients with temporal lobe lesions not involving the auditory cortex

Fig 26 compares the mean values for conventional audiometry of the ipsi and contralateral ears in nine patients with *temporal lobe disorders It is* clearly seen that there was no difference in

performance between the ipsi- and contralateral ears on the tone- and speech audiograms. The mean discrimination scores for different forms of distorted speech tests are given in fig. 27. Only very small differences in performance were found between ipsi- and contralateral ears in the test group. All patients were tested at 35 dB SL and at that level the mean scores were almost identical for both ears. Also no roll-over phenomenon was observed in this group compared with group I.

II b – Patients with temporal lobe lesions, close to auditory cortex

Fig. 28 gives the mean values found at conventional audiometry in six patients with temporal lobe lesions close to the auditory cortex. Both ordinary tone and speech audiograms

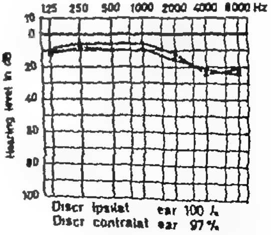

Fig. 28. Mean values of the tone- and speech audiograms in 6 patients with temporal lobe lesions, situated close to auditory cortex.

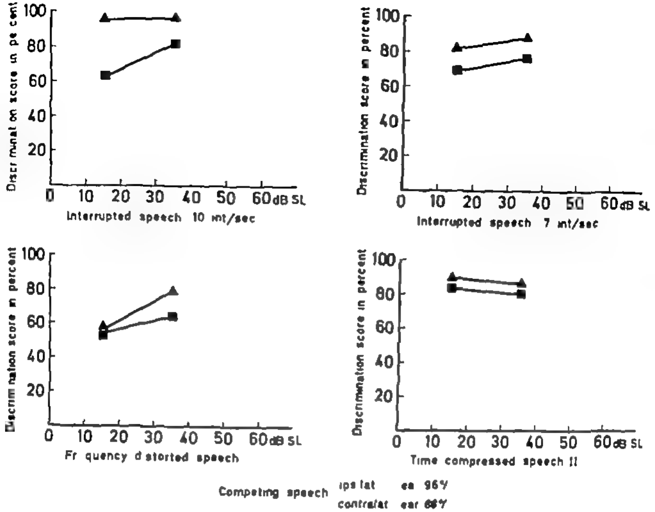

Fig 29 Mean discrimination scores for the ipsi- and contralateral ears at five different forms of distorted speech audiometry in 6 patients with temporal lobe lesions situated close to auditory cortex

showed normal values with only minor differences between the ipsi and contralateral ears When tested with distorted speech a certain difference was found between the ipsi and the contralateral ears (fig 29) The differences were most pronounced for the interrupted speech tests while the mean scores achieved by the ipsi and contralateral ears for time – compressed speech with a speech rate of 290 wpm were fairly equal As *none of the patients was tested at 50 dB SL, the* roll-over phenomenon could not be evaluated

III – Patients with intra-cranial tumours in other parts of the hemispheres

Only three patients belonged to this group There fore no mean values were calculated either for

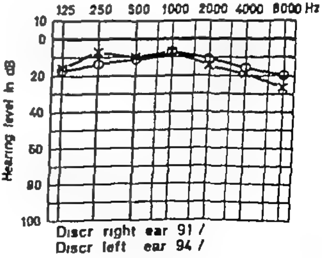

Fig 30 Mean tone- and speech audiogram in 4 patient with brai tem tumou s

conventional or for distorted speech audiometry. As shown in fig. 22 the performance in the special hearing tests was quite normal. Similar normal audiological findings were also obtained in the other two cases.

IV – Patients with brain stem lesions

In the four patients with a brain stem lesion the latter was localized mainly to the right side of the brain stem. The mean tone and speech audiograms for the right and left ears were calculated and the results obtained were within normal values (see fig. 30). The results of distorted speech audiometry in a patient with a brain stem lesion are given in fig. 23. Corresponding results were also obtained in the three other patients. Supplementary audiological tests, comprising directional hearing test, determination of the stapedial reflex threshold and tone-decay test were also performed and clearly suggested a lesion of the brain stem.

DISCUSSION OF RESULTS

The mean hearing thresholds for pure tones (see figs 24, 26, 28 and 30) showed only minor differences between the ipsi- and contralateral ears in the higher frequency range in group I. In groups II-IV the tone thresholds were largely equal for both ears. Noteworthy is the small difference in performance on undistorted speech audiometry between the ipsi- and contralateral ears in group I. In spite of fairly large destructive lesions involving the auditory cortex the mean discrimination score on the contralateral ear was only reduced by 11%. Five of the patients achieved normal scores, while the other six had discrimination scores ranging between 72% to 88%. In group II-IV the mean scores were almost identical for both ears. Thus ordinary tone and speech audiometry yields only little diagnostic information about lesions involving the auditory cortex and pathways. When monaural distorted speech tests were applied to patients with well defined temporal lobe lesions, a striking difference in performance was found between the ipsi- and contralateral ears in group I, i.e. with lesions involving the auditory cortex.

The most sensitive tests for revealing central hearing disturbances appeared to be (fig. 25) interrupted speech test with 10 interruptions/second and time-compressed speech with a speech rate around 390 wpm. In these tests, the mean difference in discrimination between the ipsi- and contralateral ears were above 50%. Frequency distorted speech showed the smallest difference viz. 32% at 50 dB sensation level.

In group II a, with lesions distant from the auditory cortex, the mean scores coincided at 35 dB S.L. in all tests. As expected, group II b, with injuries close to the auditory cortex, showed minor differences between the ipsi- and contralateral ears. These results are not quite compatible with those obtained by Bocca (1963). He found that integration disturbances in the auditory cortex were best revealed by frequency – distorted speech, while tone – compressed and interrupted speech tests indicated lesions of the second neuron and diffuse central disorders.

The difference between Bocca's results and those obtained in this investigation might be explained by the differences in phonetic composition of the languages, but also by the test methods. In this study the subjects practiced listening to frequency – distorted speech before the actual tests were started. With no practice and with the contralateral ear tested first, the difference between the ipsi- and contralateral ear might be pronounced.

The results of competing speech tests in this study showed a mean difference in discrimination between the ears of 21% in group I. The performance on the ipsilateral ear was invariably normal, while that on the contralateral ear ranged from 57% to 96%. In patients with lesions distant from the auditory cortex the mean difference was only 3%, while the corresponding figure for those with lesions close to auditory cortex was 12%. These differences are smaller than those found by Jerger (1964) in the same type of test, but the achieved results in this study suggest that this binaural test is valuable for revealing central auditory disturbances.

In patients with lesions outside the temporal lobe, the results of tests with distorted speech in three patients studied were normal, i.e., no difference in performance between the ears. These results were expected as the results of tests with low-redundant speech were normal in group II a.

The validity of auditory tests for diagnosing brain stem lesions is not so well established as that of cortical auditory tests.

Brain stem involvement usually results in auditory dysfunctions such as more or less reduced

pure tone thresholds, decreased perception of undistorted speech positive tone decay test and recruitment phenomenon varying from absent to complete as reviewed by Eichel et al (1966) and Parker et al (1968) The directional hearing is abnormal (Nordlund 1963) Parker also found a typical tone perversion in cases with brain stem lesions. Test results with distorted speech have shown (Bocca 1958 Calearo and Antonelli 1963 1968 Antonelli 1970a Jerger 1964 1970c) that low scores were obtained in the ipsilateral ear in patients with nuclear lesions while involvement of the pathways after the crossing reduced the score of the contralateral ear The change in discrimination ability is often bilateral both for undistorted and distorted speech. This is due to the fact that the cochlear nuclei are located so close to each other in the floor of the fourth ventricle that a tumour in this region can very easily impair hearing on both sides In the four cases in this study the tumours were situated mainly to the right side of the brain stem and the scores for distorted speech were also much lower on the right side than on the left (see fig. 23) This indicates that the tumour had infiltrated mainly the right cochlear nuclei and had not grown rostrally in the region of the olivary complex Similar results were obtained in the three other patients with brain stem tumours.

The patients in group I had right sided lesions, except in one case thus a difference in performance between the right and left auditory cortex could not be evaluated However Calearo and Antonelli (1963) found no difference in performance between right and left sided lesions in distorted speech tests and there is no evidence arguing against this finding in monaural test situations

The roll-over phenomenon has been demonstrated by Bocca et al (1963) (cf figs 15 21 22) in brain stem and temporal lobe lesions, but the possible cause of this phenomenon has not been discussed It is noteworthy that the roll-over effect was also demonstrable on the ipsilateral side (cf fig 18) on presentation of frequency – distorted speech. Jerger (1970a) clearly demonstrated the phenomenon in patients with eighth nerve disorders as well as in 3 out of 6 patients with brain stem injuries

In the present study the roll-over effect was seen in group I in the test with 10 interruptions/second and frequency – distorted speech but only for the contralateral ear The performance on the ipsilateral side remained the same or increased slightly when the intensity of the speech signals was increased No explanation can be offered for the roll-over phenomenon In some but not all, patients with auditory cortical involvement the discomfort level of undistorted speech was determined and found to be normal for both ears

General discussion of audiological test results in patients with intra-cranial lesions

Audiological tests for evaluation of disturbances in the central hearing mechanism are restricted by the elusive diagnostic methods applied in these disorders. In contrast with the peripheral auditory system, where signs of injuries can be revealed easily, the central auditory pathways and cortex may be seriously damaged with very little evidence of neurological deficits.

As have been discussed in part III, it is possible to evaluate changes in the central hearing mechanism by means of low-redundant speech tests (Bocca et al 1954, 1963, Matzker 1959, Jerger 1960, 1964, Lindén 1960, Feldmann 1964, 1967, Kimura 1961, Lynn 1972 and others).

The aim with the present study was to standardize different forms of distorted speech audiometry and to apply these tests, together with ordinary audiometry, to patients with welldefined intra-cranial lesions. The material consisted of thirty-three patients, twenty-six of whom had unilateral lesions in the *temporal lobe*, either on the right side or the left. The patients with temporal lobe lesions were classified according to the location and extent of the lesion into three groups, i.e. lesions involving the auditory cortex (I), lesions distant from the auditory cortex (II a) and those with lesions close to the auditory cortex (II b). The different tests with low-redundant speech audiometry included interrupted speech with 10 and 7 interruptions/sec. (time – compressed speech with a speech rate of around 290 word frequency – distorted speech and competing test (see side 43).

The mean hearing thresholds for pure tones were calculated for the ipsi- and contralateral ears in each group. It is noteworthy that even in group I there were only minor differences between the ears in the high frequency range. The observed difference between the ears is probably an effect of the cortical and subcortical dysfunction, as raised intra-cranial pressure should cause a symmetric decrease in pure tone hearing, especially in the high frequency range (von Wildhagen 1954, Jatho 1954, Hansen and Reske-Nielsen 1963). The differences obtained on the tone audiogram were however too small to permit a topical diagnosis. The results in this study agree fairly well with those of other authors (Goldstein 1956, Bocca and Calearo 1963, Jerger 1960 et al, 1964, Kimura 1961 a, b) and are also supported by experimental studies on animals (Butler et al 1951, 1957, Neff 1958, Tunturi 1960, Meyer et al 1952). The animal studies showed that bilateral ablation of auditory areas can be done without any consequent change in the discrimination of frequency and intensity of pure tones.

The concept of cortical deafness in bilateral lesions in man, reflected in decreased pure tone hearing, has been the subject of some controversy. Hearing loss, thought to be due to lesions in both posterior temporal lobes has been reported in early studies (Siebenmann 1896, Mott 1907, Henschen *1917*, *Bramwell 1927* and others). These reports however have not been universally accepted as representative of cortical deafness, as no analyses were made of premorbid auditory function, the degree of presbyacusis, earlier head trauma, presence of other systemic diseases etc. Thus DiCarlo et al (1962) denies the existence of even "a single convincing case study in which there is an unequivocally measured reduction in (auditory) sensitivity with a clearly demonstrable CNS lesion and no demonstrable peripheral lesion".

Jerger et al (1969), however, demonstrated advanced bilateral hearing loss in a patient who sustained two separate cerebral hemisphere infarctions with maximal damage in both temporal lobes. Both tone and ordinary speech tests showed a pronounced hearing loss initially, but with fairly quick recovery to almost normal hearing.

The intelligibility of undistorted speech audiometry showed only a small difference in discrimination between the ipsi- and contralateral ears in the patients with lesions involving the auditory

pure tone thresholds, decreased perception of undistorted speech positive tone decay test and recruitment phenomenon varying from absent to complete as reviewed by Eichel et al (1966) and Parker et al (1968) The directional hearing is abnormal (Nordlund 1963) Parker also found a typical tone perversion in cases with brain stem lesions. Test results with distorted speech have shown (Bocca 1958 Calearo and Antonelli 1963 1968 Antonelli 1970a Jerger 1964 1970c) that low scores were obtained in the ipsilateral ear in patients with nuclear lesions, while involvement of the pathways after the crossing reduced the score of the contralateral ear The change in discrimina tion ability is often bilateral both for undistorted and distorted speech This is due to the fact that the cochlear nuclei are located so close to each other in the floor of the fourth ventricle that a tumour in this region can very easily impair hearing on both sides. In the four cases in this study the tumours were situated mainly to the right side of the brain stem and the scores for distorted speech were also much lower on the right side than on the left (see fig. 23) This indicates that the tumour had infiltrated mainly the right cochlear nuclei and had not grown rostrally in the region of the olivary complex. Similar results were obtained in the three other patients with brain stem tumours

The patients in group I had right-sided lesions, except in one case thus a difference in perfor between the right and left auditory cortex not be evaluated However Calearo and An (1963) found no difference in performance be right and left sided lesions in distorted speech and there is no evidence arguing against this f in monaural test situations.

The roll-over phenomenon has been d strated by Bocca et al (1963) (cf figs 15 21 brain stem and temporal lobe lesions, bu possible cause of this phenomenon has not discussed It is noteworthy that the roll-over was also demonstrable on the ipsilateral s fig 18) on presentation of frequency – dis speech. Jerger (1970a) clearly demonstrate phenomenon in patients with eighth nerv orders as well as in 3 out of 6 patients with stem injuries

In the present study the roll-over effect wa in group I in the test with 10 interruptions/s and frequency – distorted speech but only f contralateral ear The performance on the lateral side remained the same or increased s when the intensity of the speech signals increased No explanation can be offered f roll-over phenomenon In some but no patients with auditory cortical involvemen discomfort level of undistorted speech was d mined and found to be normal for both ears

VI Summary

Central hearing disorders due to injuries in the central hearing pathways and auditory cortex cannot be revealed by ordinary tone and speech audiometry. With each cochlea bilaterally represented in the auditory cortex and with junctions at different levels, there is a high intrinsic redundancy in the hearing system. There is also a high extrinsic redundancy in undistorted speech, with superfluous information in the speech signals. However, by reduction of this information by various forms of distortions of the speech, hearing can be challenged and disturbances in the central hearing mechanism can then be diagnosed.

The aim of the present work was to design and standardize a new Swedish test material for distorted speech audiometry and to evaluate the effect of peripheral and central hearing disorders on the performance of these tests.

The distorted speech test battery comprised seven tests, viz., three forms of interrupted speech with 10, 7 and 4 interruptions/sec., two forms of time-compressed speech with speech rates of 220 and 290 wpm, respectively, frequency-distorted speech, and a test with competing speech.

Each test contained 100 sentences, distributed among four lists of equal length. One exception was frequency-distorted speech, where each list contained 17 sentences. The performance-intensity curves were based on 65 young persons with normal hearing, and the discrimination scores at 35 dB S.L. were above 90% in all tests except for interrupted speech with 4 interruptions/sec. When the test results were analysed according to the test sequence of the lists, it was found that practice had an effect on the discrimination of frequency-distorted speech, an observation which had not been known or taken into account in previous investigations. The first list in frequency-distorted speech was therefore used as a practice list. The other three lists were pooled and divided into two lists. The performance on distorted speech was also estimated on subjects, 50–60 years old, with normal hearing. A noteworthy finding was that in spite of normal hearing, as judged from the tone audiogram, the performance was not so good as by young normals. The tests also revealed that practice has a certain effect on all tests, which implies the elderly have to listen to a whole list to obtain reliable results, while young normals require only 7 or 12 sentences.

After standardization on 105 normals, the test battery included the test with 7 interruptions/sec., frequency-distorted speech, preceded by practice, time-compressed speech with the fastest speech rate, i.e., 290 wpm, and competing speech test. Examination of young persons with the whole test battery requires about 30 minutes. Examination of elderly patients, where two lists must be used in each test, requires 40–50 minutes.

The test battery was then used on patients with peripheral hearing loss. As expected, deteriorated hearing due to middle-ear changes had no effect on the test results. Provided that the intensity is raised enough to compensate for the attenuation in the middle ear, such hearing loss will not affect the results of distorted speech tests. In cochlear lesions, however, the tests revealed that persons with acquired lesions found it very *difficult* to manage these tests. No such difficulty was encountered by patients with congenital cochlear lesions of the same magnitude.

In order to evaluate variations of the performance on distorted speech with the site of an intra-cranial lesion, thirty-three patients with brain injuries were tested. The patients were randomly distributed among four groups.

Twenty-six patients had temporal lobe lesions, either on the right side or on the left. None of those with left-sided injuries showed signs of aphasia.

Of those patients with temporal lobe lesions, the tumours presumably involved the auditory cortex in eleven. The results of tests with distorted speech showed large differences in performance between

cortex. The discrepancy noted between the ears however did not permit any conclusions about the location or extent of the lesions, either from the mean values calculated or from the results in the individual patient In the other groups the perfor mance on both ears was largely equal The findings in this study are in agreement with those of *Goldstein (1956) Bocca et al (1954 1955 1963)* Jerger (1960 1964) and others.

In elderly patients there is often a decrease in discrimination of undistorted speech that is worse than might be expected from the tone audiogram. (Gaeth 1948 Pestalozza et al 1955 Schuknecht 1955 Hinchcliffe 1958 Glorig et al 1962 and others) This phenomenon is often referred to as phonemic regression" according to Gaeth, and is ascribed to degenerative changes in the central hearing pathways and cortex In this study seven patients in group I were 50–63 years old while the other four were younger The mean discrimination score on the ipsilateral ear was normal i.e., above 90 % in all patients *This performance in discrimi nation thus indicates that age had no notable in* fluence on the test results of ordinary speech test

When distorted speech audiometry was applied to patients with lesions involving the auditory cortex, there was found differences in discrimina *tion between the ipsi and contralateral ears around 50 % with interrupted speech tests and* time-compressed speech

Frequency-distorted speech showed the smallest differences between the ears as did competing speech test where the discrimination scores on the contralateral ear varied considerably

These findings are not in agreement with those of Bocca and his group (1963) Matzker (1959) Jerger (1960 1964 1970c) Kimura (1961) Feld mann (1964 1967) and others, who found fre quency-distorted speech and different forms of binaural competing tests to be the most sensitive tool *for revealing auditory cortical pathology*

The differences between the results in this study and those reported by other authors can probably be explained by both differences in the test methods and languages used

In brain stem pathology the distorted speech tests were very sensitive for revealing disturbances in the cochlear nuclei and the ascending auditory pathways. *The findings in this study are quite in* agreement with those of Bocca et al (1963) Jerger (1964) Calearo and Antonelli (1968) Matzker (1959) and others. The distorted speech tests thus are a valuable complementary to other audiologi cal *tests for diagnosing brain stem lesions.*

As expected the test results with distorted speech audiometry varied *from patient to patient* Even if the extent and location of the lesion could be classified fairly well it was difficult to evaluate concommitant effects of focal edema the degree of infiltrative growth of the tumours, displacement of *normal structures raised intra-cranial pressure* and probably also retrograde degeneration of the auditory pathways. With this in mind each case with an intra-cranial lesion must be regarded separately when evaluating the test results with distorted speech audiometry The mean discrimi nation scores shown in figs 25 27 and 29 are given just to facilitate a general survey of the findings obtained by low redundant speech tests.

CONCLUDING REMARKS

Ordinary audiometric tests, with pure tone and undistorted speech audiometry give very little if any diagnostic information about disturbances in the central hearing pathways and auditory cortex On the other hand the results with distorted speech tests clearly showed that intra-cranial le *sions involving* the auditory cortex and adjacent hearing pathways markedly reduce the perfor mance on the ear contralateral to the lesion, compared with the results obtained by the ipsila teral ear Temporal lobe lesions *not* involving the auditory cortex gave normal test results *In brain* stem lesions, the ipsilateral ears achieved reduced scores on distorted speech audiometry indicating involvment of the cochlear nuclei on the same side

Even if the most sensitive tests for revealing central hearing disturbances seems to be interrup *ted speech tests and time-compressed speech* it is evident from the cases illustrated in figs 1?–16 and 31–36 that no one test by itself can reveal a central auditory lesion A firm diagnosis requires evaluation of the results of four or five different *forms of distorted speech tests*

Distorted speech audiometry of the different forms standardized and used in this study thus demonstrate a substantial value for the purpose of diagnosing dysfunctions involving the auditory cortex central hearing pathways and brain stem

VI Summary

Central hearing disorders due to injuries in the central hearing pathways and auditory cortex cannot be revealed by ordinary tone and speech audiometry. With each cochlea bilaterally represented in the auditory cortex and with junctions at different levels, there is a high intrinsic redundancy in the hearing system. There is also a high extrinsic redundancy in undistorted speech, with superfluous information in the speech signals. However, by reduction of this information by various forms of distortions of the speech, hearing can be challenged and disturbances in the central hearing mechanism can then be diagnosed.

The aim of the present work was to design and standardize a new Swedish test material for distorted speech audiometry and to evaluate the effect of peripheral and central hearing disorders on the performance of these tests.

The distorted speech test battery comprised seven tests, viz., three forms of interrupted speech with 10, 7 and 4 interruptions/sec., two forms of time – compressed speech with speech rates of 220 and 290 wpm, respectively, frequency-distorted speech, and a test with competing speech.

Each test contained 100 sentences distributed among four lists of equal length. One exception was frequency-distorted speech, where each list contained 17 sentences. The performance-intensity curves were based on 65 young persons with normal hearing, and the discrimination scores at 35 dB S.L. were above 90% in all tests except for interrupted speech with 4 interruptions/sec. When the test results were analysed according to the test sequence of the lists, it was found that practice had an effect on the discrimination of frequency distorted speech, an observation which had not been known or taken into account in previous investigations. The first list in frequency-distorted speech was therefore used as a practice list. The other three lists were pooled and divided into two lists. The performance on distorted speech was also estimated on subjects, 50–60 years old, with normal hearing. A noteworthy finding was that in spite of normal hearing, as judged from the tone audiogram, the performance was not so good as by young normals. The tests also revealed that practice has a certain effect on all tests, which implies the elderly have to listen to a whole list to obtain reliable results, while young normals require only 7 or 1 sentences.

After standardization on 105 normals, the test battery included the test with 7 interruptions/sec., frequency-distorted speech, preceded by practice, time-compressed speech with the fastest speech rate, i.e., 290 wpm, and competing speech test. Examination of young persons with the whole test battery requires about 30 minutes. Examination of elderly patients, where two lists must be used in each test, requires 40–50 minutes.

The test battery was then used on patients with peripheral hearing loss. As expected, deteriorated hearing due to middle-ear changes had no effect on the test results. Provided that the intensity is raised enough to compensate for the attenuation in the middle ear, such hearing loss will not affect the results of distorted speech tests. In cochlear lesions, however, the test revealed that persons with acquired lesions found it very difficult to manage these tests. No such difficulty was encountered by patients with congenital cochlear lesions of the same magnitude.

In order to evaluate variations of the performance on distorted speech with the site of an intra-cranial lesion, thirty-three patients with brain injuries were tested. The patients were randomly distributed among four groups.

Twenty-six patients had temporal lobe lesions either on the right side or on the left. None of those with left-sided injuries showed signs of aphasia.

Of those patients with temporal lobe lesions, the tumours presumably involved the auditory cortex in eleven. The results of tests with distorted speech showed large differences in performance between

the ipsi and contralateral ears especially in the test with 10 interruptions/sec. and time-compressed speech. The smallest difference between the ears was found for frequency-distorted speech These results contrast with those obtained by Bocca and his group who found frequency-distorted speech to be the most sensitive test for revealing disturbances in the auditory cortex

Nine of the patients with temporal lobe injuries had lesions situated at some distance from auditory cortex i.e in the temporal pole The test results with distorted speech tests revealed no differences between ipsi and contralateral ears There were also six patients in whom the lesions were thought to be very close to the auditory cortex In these patients the mean difference between the ears in distorted speech tests was small as expected

Three patients had tumours situated in other parts of the hemispheres and in these too distorted speech audiograms were normal In four patients with mainly right-sided tumours in the brain stem distorted speech tests gave markedly reduced scores on the right ear These results suggest that it was mainly the cochlear nuclei on the same side that were injured

The results thus clearly showed that tests with distorted speech audiometry can reveal lesions involving the auditory cortex and the central hearing pathways but not injuries situated outside this fairly welldefined area When the case history and the results of common diagnostic tests indicate a lesion possibly involving the central auditory pathways and cortex, the distorted speech tests presented here can give a correct diagnosis already in the early stages of the disease

It is clear however that this category of patients are relatively few The above mentioned possibilities of diagnosing central hearing disturbances might prove useful in the elucidation of a much more extensive problem, i e of those dysfunctions in hearing which are embraced in the term presbyacusis. There is evidence suggesting that deterioration of hearing with advancing age comprises peripheral and central components which cannot be distinguished from each other by ordinary audiological tests

Zusammenfassung

Hörstörungen auf Grund von Schädigungen in den zentralen Hörbahnen und der primären Hörrinde können nicht mit Ton- und Sprachaudiometrie diagnostiziert werden. Bei normalem Sprechen liegt ein Überschuss von Information für den Hörenden vor. Eine Reduzierung dieser Information durch verschiedene Formen von Sprachdistorsion belastet die Hörfunktion und Störungen in dem zentralen Hörmechanismus können auf diese Weise diagnostiziert werden.

Die Zielsetzung der Arbeit war, neues schwedisches Sprachmaterial für erschwerte Sprachaudiometrie zu standardisieren und den Effekt der Auffassbarkeit dieser Teste bei peripheren und zentralen Hörschädigungen zu beurteilen. Die Testserien umfassen 7 verschiedene Teste: 3 Formen von aufgesplittertem Sprechen mit 10, 7 resp. 4 Unterbrechungen per Sekunde, 2 Formen von zeitkomprimiertem Sprechen mit einer Sprechgeschwindigkeit von 220 resp. 290 Worten per Minute, frequenzfiltriertes Sprechen und ein Sprechen mit "competing speech".

Jeder Test enthält 100 Sätze, verteilt auf 4 Listen von gleicher Länge. Eine Ausnahme macht frequenzfiltriertes Sprechen, wo jede Liste 17 Sätze enthält. Die verschiedenen Teste wurden bei 85 jungen Versuchspersonen mit normalem Gehör standardisiert. Die Auffassbarkeit bei 35 dB S.L. war über 90 % in allen Testen mit Ausnahme des aufgesplitterten Sprechens mit 4 Unterbrechungen per Sekunde. Als die Testresultate mit Rücksicht auf die Testordnung der Listen innerhalb jedes Tests analysiert wurden, fand man, dass Übung das Testresultat bei frequenzfiltriertem Sprechen beeinflusste.

Die Auffassbarkeit von erschwertem Sprechen wurde auch bei [illegible] Versuchspersonen im Alter von 50 bis 60 Jahren und mit normalem Gehör beurteilt. Ein anmerkenswerter Befund war, dass trotz normalen Gehörs laut Tonaudiogramm, eine gesenkte Diskriminationsfähigkeit vorlag, verglichen mit jüngeren Normalhörenden. Die Untersuchungen machten auch deutlich, dass Übung einen gewissen Einfluss auf alle Teste hatte.

Nach der Standardisierung bei 105 Normalhörenden besteht die Testserie aus folgenden Versuchen: aufgesplittertes Sprechen mit 10 resp. 7 Unterbrechungen per Sekunde, frequenzfiltriertes Sprechen, zeitkomprimiertes Sprechen mit einer Sprechgeschwindigkeit von 290 Worten per Minute samt "competing speech" Test.

Wie erwartet zeigten Patienten mit peripherer Schwerhörigkeit auf Grund von Schädigungen im Mittelohr normale Testresultate. Wenn die Intensität lediglich erhöht wurde, um Schalleitungsstörungen zu kompensieren, wurde das Resultat der erschwerten Sprachaudiometrie nicht beeinflusst. Bei Innenohrstörungen zeigte es sich dagegen, dass Patienten mit erworbenen Innenohrstörungen eine sehr niedrige Auffassbarkeit von erschwertem Sprechen hatten. Derartige Schwierigkeiten zeigten sich nicht bei Patienten mit angeborenen Innenohrstörungen vom selben Schwierigkeitsgrad.

Um die Auffassbarkeit von erschwerter Sprachaudiometrie bei zentralen Hörstörungen zu beurteilen, wurden 33 Patienten mit intrakraniellen Tumoren getestet. Die Patienten wurden je nach der Lokalisation der Schädigung in 4 Gruppen aufgeteilt, und die Klassifizierung wurde von einem Neurochirurgen und einem Neuroradiologen vorgenommen. 26 Patienten hatten Temporallappenläsionen, entweder auf der rechten oder linken Seite. Keiner mit linksseitigen Störungen wies Zeichen von Aphasie. In 11 Fällen handelte es sich um Tumoren, welche die primäre Hörrinde betrafen. Die Resultate von Testen mit erschwerter Sprachaudiometrie zeigten sehr grosse Unterschiede in der Auffassbarkeit zwischen ipsi- und kontralateralem Ohr in dieser Gruppe, speziell für den Test mit 10 Unterbrechungen per Sekunde und zeitkomprimiertem Sprechen. Der kleinste

Unterschied zwischen ipsi — und kontralateralem Ohr zeigte sich bei dem frequenzfiltrierten Sprechen. Diese Resultate stehen im Gegensatz zu denen, Die Bocca und seine Gruppe fanden

9 der Patienten mit Temporallappenlasionen hatten Schadigungen, die auf Abstand von der primaren Horrinde lagen. Die Resultate von erschwerter Sprachaudiometrie zeigten in diesen Fällen keine Unterschiede zwischen ipsi — und kontralateralem Ohr 6 Patienten hatten Schadigungen im Temporallappen sehr nah bei der primaren Horrinde, und dort zeigten die Teste — wie erwartet — einen gewissen Unterschied zwischen ipsi- und kontralateralem Ohr

3 Patienten hatten Tumoren, die in anderen Teilen der Hemispharen lagen und diese hatten ebenfalls normale Auffassbarkeit von erschwertem Sprechen. Bei 4 Patienten mit hauptsachlich rechtsseitigen Tumoren im Bereich der Brucke zeigte die erschwerte Sprachaudiometrie markant gesenkte Werte auf dem rechten Ohr was für eine Schadigung kaudal der oberen Olivekerne spricht

Die Testresultate zeigen somit deutlich, dass erschwerte Sprachaudiometrie die Moglichkeit gibt Schadigungen, die die primare Horrinde und naheliegende zentrale Horbahnen umfassen, zu diagnostizieren dagegen nicht Schadigungen, welche ausserhalb dieses gut abgegrenzten Gebietes liegen Wenn auf Grund des Krankheitsverlaufes und gewohnlicher diagnostischer Untersuchungen Ursache vorliegt eine Schadigung, welche die zentralen Horbahnen und die primare Horrinde angreift zu vermuten so kann erschwerte Sprachaudiometrie zeitig zu einer korrekten Diagnose führen.

Es ist jedoch klar dass diese Kategorie von Patienten relativ klein ist. Die aufgezeigten Moglichkeiten, zentrale Horschädigungen zu diagnostizieren, deuten auf verbesserte Methoden die Schwerhorigkeit zu beurteilen welche in dem Begriff presbyacusis zusammengefasst ist.

Bei herabgesetztem Gehor das eine Folge hoheren Alters ist, gibt es Indikation auf einen variierenden Grad von sowohl peripheren wie zentralen Horstorungen, welche mit konventionellen audiologischen Testmethoden nicht von einander unterschieden werden konnen.

VII Acknowledgements

The present investigation has been carried out at the Audiological Department, Ear-Nose- and Throat Clinic, University of Gothenburg, Sweden.

I take this opportunity of expressing my sincere gratitude to Professor Gösta Herberts, head of the Department of Otorhinolaryngology, for his positive criticism and great interest shown; my teacher Ass. Professor Gunnar Lidén, head of the Audiological Department, for instructions in the field of audiology, guidance and never-tiring interest throughout the work; Doctor Sten Lindgren, Department of Neurosurgery, for stimulating discussions, constructive criticism and expert advice in the field of neurosurgery; Doctor Sture Stattin, Department of Neuroradiology, for generous expert advice and help in the evaluation of the X-ray findings; Mr Göte Björkman and Roland Nilsson, research engineers, for skilful technical assistance and advice.

I am greatly indebted to Mrs Birgitta Jonsson and Mrs Margareta Larsson for valuable help with the performance of the tests, and to Mr Ingolf Johansson for drawing the illustrations. I also thank Mr L. James Brown for correction of the English text and Miss Ragnor Joelsson for typing the manuscript.

Thanks go also to Hans Wedel, Fil. lic., Department of Mathematics, Chalmers University of Technology, for stimulating discussions concerning the statistical analyses.

Finally, I am very thankful to all my colleagues here and at the Departments of Audiology and Neurosurgery in Stockholm and Uppsala, for helping me realize these studies.

This study was supported by grants from Statens Medicinska Forskningsråd B 73-61P-4022-01 and from Göteborgs Läkaresällskap.

Unterschied zwischen ipsi – und kontralateralem Ohr zeigte sich bei dem frequenzfiltrierten Sprechen. Diese Resultate stehen im Gegensatz zu denen, Die Bocca und seine Gruppe fanden.

9 der Patienten mit Temporallappenlasionen hatten Schädigungen die auf Abstand von der primaren Horrinde lagen. Die Resultate von erschwerter *Sprachaudiometrie* zeigten in diesen Fallen keine Unterschiede zwischen ipsi – und kontralateralem Ohr 6 Patienten hatten Schadigungen im Temporallappen sehr nah bei der primaren Horrinde und dort zeigten die Teste – wie erwartet – einen gewissen Unterschied zwischen ipsi- und kontralateralem Ohr

3 Patienten hatten Tumoren, die in anderen Teilen der Hemispharen lagen und diese hatten ebenfalls normale Auffassbarkeit von erschwertem Sprechen. Bei 4 Patienten mit hauptsachlich rechtsseitigen Tumoren im Bereich der Brucke zeigte die erschwerte Sprachaudiometrie markant gesenkte Werte auf dem rechten Ohr was für eine Schadigung kaudal der oberen Olivekerne spricht.

Die Testresultate zeigen somit deutlich, dass erschwerte *Sprachaudiometrie* die Moglichkeit gibt, Schadigungen, die die primäre Horrinde und naheliegende zentrale Horbahnen umfassen, zu diagnostizieren dagegen nicht Schadigungen, welche ausserhalb dieses gut abgegrenzten Gebietes liegen. Wenn auf Grund des Krankheitsverlaufes und gewohnlicher diagnostischer Untersuchungen Ursache vorliegt eine Schadigung, welche die *zentralen Horbahnen und die primare Hörrinde* angreift zu vermuten so kann erschwerte Sprachaudiometrie zeitig zu einer korrekten Diagnose führen.

Es ist jedoch klar dass diese Kategorie von Patienten relativ klein ist. Die aufgezeigten Moglichkeiten, zentrale Horschadigungen zu diagnostizieren deuten auf verbesserte Methoden die Schwerhorigkeit zu beurteilen, welche in dem Begriff presbyacusis zusammengefasst ist.

Bei herabgesetztem Gehor das eine Folge hoheren Alters ist, gibt es Indikation auf einen variierenden Grad von sowohl peripheren wie zentralen Horstorungen, welche mit konventionellen audiologischen Testmethoden nicht von einander unterschieden werden konnen.

Appendix

TEST LISTS (1–4) USED FOR TIME-COMPRESSED SPEECH WITH A SPEECH RATE OF 290 WPM

List 1 (1)

Lennart slog sönder det stora fönstret.
Han åker kanske till landet på söndag
Svenskarna trivs med solen i Spanien
Kalle duskade efter middagen.
Vattnet är ännu för kallt för bad
Måste jag läsa boken i kväll?
Tänder du lampan, så ser du bättre
Läxorna först och nöjena sedan
Våga inte komma för sent
Planen är full av gammalt löv
Kan du inte träffa prick?
Gråt inte på gammalt barn
Hur många syskon har Lena?
Är du aldrig rädd för hunden?
Granen barrar före påsk
Bruden bar krona och långa handskar.
Lockigt hår är sött på småbarn
Hur lång är vägen till Stockholm
Svenska flaggan hälsades ombord
Vinden slet sönder alla segel
Båda gässen simmar inte i dammen
Göteborg har landets största hamn
Roddaren kämpade länge i båten
Cigarrett förpestar luften i rummet.
Varför bråkar Göran och Pelle

List 2 (2)

Posten kommer varje dag
Räven plundrade fågelns bo
Tåget spårade ur i kurvan
Ost och vin är gott tillsammans.
Blommiga byxor är högsta mode
Bullar och mjölk är bra som mellanmål
Rött ljus hindrar trafiken
Kaffe på maten avslutar middagen.
Porten låses klockan tio
Glass är både gott och nyttigt.
Gubben läste sin tidning på natten.
Kronor och ören är svenska mynt.
Italiens karta liknar en stövel
Höstens regn har skadat marken.
Billiga ljus brukar droppa och ryka
Bilar och cyklar trängdes på gatan.
Pojken ramlade och slog sitt knä.
Båtar och bryggor hör sommaren till.
Den nya terminen har just börjat
Vänta en stund så kommer doktorn.
Frisk luft och motion gör nytta.
Det härliga lövet är nästan slut.
Var snäll mot djuren du möter i skogen.
Skogen på landet är stadsbornas paradis
Annas syster säljer bilar

List 3 (3)

Lärkan är alltid välkommen gäst.
Grevinnan bar långa halsband och ringar
Tårtan måste ha tio ljus.
Kola är inte bra för tänderna.
Alla stolarna skall målas blå
Kungar brukar bli mycket gamla.
Raketen sprängdes i luften i natt.
Mamma fick ont i örön och hals.
Många trivs med att vandra i fjällen.
Sanning ingår i skolans träning
Jag har beställt en vit telefon.
Varför är alla träd så gröna?
Måste du köpa en blommig klänning
Kan du visa mej vägen till Malmö
Gården är inte utsatt på kartan.
Tvätten torkar fort i solen.
Skrunda inte med koppar och fat.
Golvet är nybonat och väldigt halt.
Du får gärna torka disken.
Sprutan dronen och lyssna noga.
Gumman säljer fisk på torget.
Farmor hade en schal om halsen.
Lägg en ren duk på bordet.
Tomten kommer till lydiga barn.
Hundarna sprang och lekte i solen.

CONTENTS

Foreword

The behavioral investigations reported in this monograph were conducted by CPT George Luz (Ph D) LTC John Fletcher (Ph D) and Dr James Mosko at the Experimental Psychology Division of the US Army Medical Research Laboratory Fort Knox, Kentucky 401 1 Professor Michel Loeb (Ph.D) of the University of Louisville initiated the project Techni l assistance was provided by Mr Carl Guthrie and animal testing was done by Mr William Cooper and Mr David Duffy Ear surgery was performed by Maj William Fravel M D of the Ireland Army Hospital Fort Knox Also closely involved with the project were Dr George Harker Director of the Experimental Psychology Division and COL Nichola Conte M D Commanding Officer of the Medical Research Laboratory of Fort Knox

The sacrifice and initial histological preparation of the subjects were carried out at Fort Knox by Drs Kazuo Chiba M D and Armando Jimenez, M D Histological preparation was continued at the Inner Ear Research Laboratory at Case-Western Reserve University Medical School Cleveland Ohio through a grant from the John A Hartford Foundation Inc. New York City (C W R U 642 5822) Final histological analyses were carried out by Drs Marilyn Pinheiro Kazuo Chiba and Valdemar Jordan M D Director of the Inner Ear Research Laboratory

Because this monograph covers the activities of two independent laboratories the three major sections have been treated as separate studies each with a different set of authors However the table of contents the bibliography and the figure numbers are used to reference all three studies as a single monograph

The Relation Between Temporary Threshold Shift and Permanent Threshold Shift in Rhesus Monkeys Exposed to Impulse Noise

by George A Luz John L. Fletcher [a] William J Fravel [a] James D Mosko[1]

INTRODUCTION

If an ear shows a measurable but reversible loss in sensitivity after known exposure to sound the loss is called temporary threshold shift (TTS). The TTS is commonly measured (in decibels) at 2 min after termination of the sound (TTS_2) A number of similarities have been observed between TTS_2 and permanent threshold shift (PTS) For example Glorig, Ward & Nixon (1961) noted that the TTS_2 at 4 kHz acquired at the end of a working day in a noisy plant seemed to be of the same magnitude as the PTS seen after nine years on the job Additional similarities between TTS and PTS have been noted by Kryter (1970)

Such apparent relationships between TTS and PTS have led several investigators to probe another hypothesis—that an individual s susceptibility to TTS is an adequate predictor of his susceptibility to PTS A number of animal studies have tested this hypothesis. All have failed to support it. Among the animals studied have been the cat (Miller Watson & Covell 1963) the rat (Herman & Clack, 1963) the rhesus monkey (Harris 1967) and the chinchilla (Ward & Nelson 1968)

Generalizing from later research these past failures were reasonable Temporary threshold shift from any particular noise exposure cannot be used as an index of an ear's general susceptibility to fatigue (Ward 1971) For example an ear s susceptibility to TTS from low frequency noise does not adequately predict its susceptibility to high frequency noise (Ward 1968) and its susceptibility to noise at one intensity may not predict its susceptibility at a higher intensity (Kryter 1970 p 168) At best TTS could only be used to pick out the most susceptible individuals within a given noise environment (e.g Pfander 1968 1969). Even this relationship has not been firmly established. Thus more studies are needed

As a test of the correlation between initial susceptibility to TTS and later susceptibility to PTS from a single noise source 10 rhesus monkeys were given behavioral audiograms and exposed repeatedly to impulse noise. After each exposure subjects were tested until recovery from TTS was complete Permanent threshold shift was measured 64 days after the last exposure

The Relation Between Temporary Threshold Shift and Permanent Threshold Shift in Rhesus Monkeys Exposed to Impulse Noise

by George A Luz, John L. Fletcher [2] William J Fravel [3] James D Mosko

INTRODUCTION

If an ear shows a measurable but reversible loss in sensitivity after known exposure to sound the loss is called temporary threshold shift (TTS) The TTS is commonly measured (in decibels) at 2 min after termination of the sound (TTS_2) A number of similarities have been observed between TTS_2 and permanent threshold shift (PTS) For example Glorig, Ward & Nixon (1961) noted that the TTS_2 at 4 kHz acquired at the end of a working day in a noisy plant seemed to be of the same magnitude as the PTS seen after nine years on the job Additional similarities between TTS and PTS have been noted by Kryter (1970)

Such apparent relationships between TTS and PTS have led several investigators to probe another hypothesis—that an individual's susceptibility to TTS is an adequate predictor of his susceptibility to PTS A number of animal studies have tested this hypothesis. All have failed to support it. Among the animals studied have been the cat (Miller Watson & Covell 1963) the rat (Herman & Clack, 1963) the rhesus monkey (Harris 1967) and the chinchilla (Ward & Nelson 1968)

Generalizing from later research these past failures were reasonable. Temporary threshold shift from any particular noise exposure cannot be used as an index of an ear's general susceptibility to fatigue (Ward, 1971) For example an ear's susceptibility to TTS from low frequency noise does not adequately predict its susceptibility to high frequency noise (Ward, 1968) and its susceptibility to noise at one intensity may not predict its susceptibility at a higher intensity (Kryter 1970 p 168) At best, TTS could only be used to pick out the most susceptible individuals within a given noise environment (e g. Pfander 1968 1969) Even this relationship has not been firmly established Thus more studies are needed.

As a test of the correlation between *initial* susceptibility to TTS and later susceptibility to PTS from a single noise source 10 rhesus monkeys were given behavioral audiograms and exposed repeatedly to impulse noise After each exposure subjects were tested until recovery from TTS was complete. Permanent threshold shift was measured [redacted] days after the last exposure.

end of the 3 sec stimulus The shock was terminated only when the animal was completely across the barrier

On the day after animals avoided the shock for 18 out of 20 trials generalization training was initiated Gradually the animals were exposed to the higher and lower frequencies to be used in threshold testing

Pre-threshold training was begun when the animals avoided the shock twice successively at each test frequency At this point attenuation of the test tones was begun usually in 10 or 20 dB steps, depending upon the animal This stage of training continued until the animals were thoroughly accustomed to changes in both intensity and order of presentation of the frequencies

Threshold procedures

Although the procedure for obtaining thresholds varied somewhat according to the stage of the experiment the basic procedure was merely a refined continuation of pre-threshold training The tone was attenuated in steps of 20 dB until the animal failed to respond then was increased by 10 dB and then further increased or decreased by 5 dB according to whether the animal responded to the increase of 10 dB His final score (in dB) for that frequency was halfway between the least intensity eliciting a response and the next lowest intensity

In obtaining any threshold it was necessary for the experimenter to be reasonably certain that the animal was attending to the signal Early in training most of the animals began orienting their intact ear toward the speaker It was assumed that this position indicated attention by the animal and care was taken to initiate the more difficult trials when the animal was in this position Shock was usually omitted on difficult trials

A modified procedure was used in evaluating temporary threshold shift. Immediately after an impulse exposure the monkey was transferred to the shuttlebox Since 1 to 3 min were required for a threshold determination, only one frequency could be studied during the first 10 min after an exposure The frequency chosen was 2 000 Hz. After the first 10 min TTS was evaluated at the additional frequencies of 1 8 and 14 kHz and thresholds were determined periodically until recovery was complete at all four frequencies During the first hour after exposure testing was carried on continuously A stopwatch was used to record the exact minute at which a determination was made For this reason the test periods were distributed randomly during the first hour Thereafter thresholds were determined at 2 4 8 hr etc until recovery to within 5 dB of preexposure threshold After continuous noise exposure only the 2 kHz threshold was tested

Schedule and sources of noise exposures

Monkeys were exposed to both continuous and impulsive noise The continuous noise used was originally recorded on an Ampex 600 tape recorder from inside an M60 main battle tank traveling on a hard surface road at 25 mph For the actual exposure a tape loop of this noise was played back amplified and fed to an Altec 515 low frequency speaker The speaker was in one corner of the anechoic chamber The sound level at 15 in. from the cone of the speaker (the level of the monkey's ear during exposure) was 110 dB as measured on the linear scale of the Bruel and Kjaer Type 2112 Audio Frequency Spectrometer A one third octave band analysis of this noise revealed a peak at 500 Hz with a negative slope of 10 dB per octave between 500 Hz and 12 000 Hz. For a graph of the analysis see Fig. 1 of Luz Fletcher Fravel & Mosko (1971)

The impulse noise was generated with a multiple spark-gap generator devised by R. W Benson and Associates The 4-gap condition was used (cf Loeb & Fletcher 1968) This condition yielded a pulse with a condensation of 168 dB and 60 μsec duration and a rarefaction of 165 dB and 100 msec dura-

others the five males (M 2 M 3 M-4 M 64 and M 25) ranged from four to eight years of age and the females (M 30 M 39 M-43 M-47 and M-49) from three to five years of age (cf Luz Fletcher Mosko & Fravel 1971 for further details)

The surgery was performed in the USAMRL surgical suite by Dr William Fravel a qualified ENT surgeon on the staff of the post military hospital

With the monkey under general anesthesia the right middle ear was approached through a post-auricular incision The posterior bony canal wall was drilled away until access to the middle ear was attained All middle ear ossicles were removed to include the foot plate The vestibule was then entered with a large curved pick and the instrument was manipulated to destroy inner ear anatomy—the free flow of inner ear fluid was controlled by packing with sterile gel foam The tympanic membrane was destroyed along with the annulus The middle ear and external bony canal were packed with gel foam the incision closed and the animal placed on postoperative antibiotics

Apparatus

A two-way shuttlebox was used for the training and testing of the monkeys In its interior it was 81 cm long 36 cm wide and 63 cm high The dividing barrier was 23 cm The sides and top were made of steel bars sunk into a sheet metal base A sheet metal pan resting on the base was filled with a 4 inch layer of Sani-Cel In addition to absorbing the droppings this material damped reflections from the base of the shuttlebox Shock to the shuttlebox was under manual control and could be applied in the following combinations left side right side left plus barrier right plus barrier barrier alone

During testing the subject was observed on a closed circuit TV Although two flood lights were needed for an adequate picture the level of illumination in the test chamber was generally low

Acoustic environment and calibration of the audiometer

The shuttlebox was placed in the center of a windowless anechoic chamber for the threshold testing Fiberglass wedges covered all six inside planes of the chamber An AR 3 speaker suspended 76 cm above the top of the shuttlebox was fed by a shielded cable which was passed through the wall of the chamber

The pure tones were generated by a Hewlett Packard oscillator gated by a Grason-Stadler vacuum tube switch and amplified by a Krohn Hite 50 watt power amplifier Transistor logic was used to control the electronic switch The signal consisted of three 0 5 sec pulses of 50 msec rise and decay time with a 0 5 sec off time At the end of 3 sec a signal light informed the experimenter that the trial had ended A Ballantine voltmeter was used to check the audiometer output voltage before each session and an Erie Frequency Counter was used to check the frequency of the stimulus before threshold determination

The resulting sound field was measured at 20 different positions within the shuttlebox A Bruel and Kjaer Audio Frequency Spectrometer (Type 2112) and 1/2 condensor microphone (4133) were used For the six audiometric frequencies used (1 2 4 8 10 and 14 kHz) the standard deviations of the SPL measures were 2 2 5 6 5 and 5 respectively The mean of these settings was used as an estimate of the sound field The audiometer system was measured at the maximum levels used for the monkeys (70–80 dB)

Training procedures

Animals with previous avoidance training required only minimal familiarization before beginning actual threshold determinations The following procedure was used with untrained animals

Twenty trials of avoidance conditioning to a 1 kHz pulsed tone at 75 dB SPL were given daily Random intervals between trials were 1 to 2 min The animals were shocked if they failed to cross the dividing barrier before the

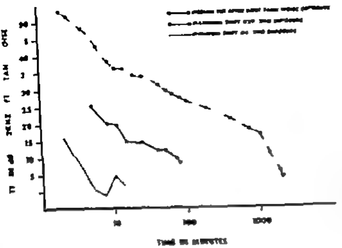

Fig 1 Recovery from temporary threshold shift after exposure to 1 min of tape recorded tank noise. The median shift seen in nine monkeys after the first exposure to this noise (solid line) is compared with the largest shift (M-39 dashed lines) and the smallest shift (M-4 dotted lines) seen after the second exposure.

recent study of lemur hearing (Mitchell et al 1970) Three lemurs showed the dip three lemurs did not. Neither sex nor age nor species could account for the difference Other studies in which the 4 kHz dip did not occur are Semenoff & Young (1964) and Fujita & Elliott (1965)

Recovery after exposure to tank noise

The 1? min exposure to the tape-recorded tank noise was relatively innocuous In fact the TTS was too transient to permit adequate testing at more than one frequency The frequency chosen was 2 kHz.

It was impossible to obtain measures of TTS at exact, prearranged intervals of time However each subject s recovery was monitored carefully enough to allow adequate interpolations for statistical comparisons Such a comparison is given in Fig. 1 which contains a recovery function based on the median TTS of nine subjects (solid lines) Because of missing data the function is only defined between 5 and 80 min after exposure Over this range the recovery is a logarithmic function of time after exposure

The median statistic is an adequate reflection of individual data With one notable exception, all subjects showed a logarithmic recovery The one exception M-43 showed a "delayed recovery" a type previously described by Ward

Both the largest and the smallest individual records of TTS were seen after the second exposure to the noise These records are also shown in Fig. 1 The animal with the least TTS M-4 had shown the second to the largest amount of TTS_2 after his first exposure In contrast, M 39 who had shown the least TTS_2 after the first exposure had the most TTS_2 after the second exposure

Most of the subjects (seven out of nine) showed less TTS_2 after the second exposure than after the first. This drop in measured TTS was not the result of an increase in the pre-exposure threshold between the first and second exposure If anything sensitivity at 2 kHz had improved (mean thresholds of 7 dB and 3 dB SPL, respectively). The group correlation between TTS on the first and second exposures was negative (−0 74)

Recovery after exposure to the two-impulse condition

In the preceding section, the TTS following exposure to tank noise was shown to recover as a linear function of the logarithm of time. This relation was expected since it had been shown to occur for animals as diverse as man (Ward et al 1958) cat (Miller et al 1963) chinchilla (Peters 1965) rat, and monkey

Table I *Sequence of exposure conditions* (in days)

	Subjects									
Exposure	4	64	3	49	39	47		43	30	_5

20 impulses				11		98				

Schedule of exposure for each subject The order in which each monkey received his first impulse exposure (Day 1) is reproduced from left to right Vertical entries record the day after the first impulse exposure on which the monkey received each successive exposure Blank entries indicate that no exposure was given

tion (when measured with a Bruel and Kjaer model 4136 microphone feeding into a Tektronix storage oscilloscope) These measurements were made at 10 in from the spark gap the level of the monkey s ear during exposure (Measurements were made without the presence of the experimental animal) Compared with impulses from typical military (Kryter & Garinther 1966) or industrial sources (Martin Atherly & Hempstock 1970) this impulse was shorter with its energy spectrum peaked at higher frequencies

Monkeys were exposed with the left ear at normal incidence to the spark gaps Successive impulses were separated by 1 sec of silence Two impulses were used for the induction of TTS while 10 or 20 impulses were used for the induction of PTS

Since one purpose of this study was to establish a relation between TTS and PTS the least noxious exposures were made first There were five presented in the same order for each of nine subjects two impulses tank noise two impulses two impulses and tank noise A tenth subject a monkey with an obvious preexperimental hearing loss was terminated after the first exposure Preceding each of these exposures the threshold sensitivity of each monkey was reevaluated At the end of this schedule the nine subjects received an exposure of 10 successive impulses In addition two monkeys manifesting no PTS from the 10 impulses received another exposure to 20 successive impulses

Adequate time was given for recovery after every exposure Since this time varied slightly from subject to subject the exact day of exposure varied between subjects The exposure schedule for each is given in Table I Recovery from the maximal impulse noise exposure was measured at 1 2 4 8 16 and 32 days A final audiogram was determined for each subject following day 64

RESULTS

Pre-exposure audiogram

For the range of frequencies tested nine of the 11 monkeys were considered normal when compared with the results of Behar et al (1965) and Stebbins et al (1966) One abnormal animal M 25 had a striking high frequency loss (a 55 dB drop in threshold between 10 and 12 kHz) The other gave ambiguous results and was dropped Although his mean thresholds were initially similar to those of the other monkeys the variance of his thresholds was large and he finally stopped responding altogether (Later histology showed this animal to have hair cell damage of unknown origin) A graphic comparison of the mean thresholds for the nine normal subjects with previous published data from the same laboratory may be found in Fig. 2 of Luz Fletcher Fravel & Mosko (1971)

The group audiogram did not show a dip at 4 000 Hz In contrast most studies of primate hearing have found a dip of insensitivity at 4 000 Hz It was first noted in the chimpanzee (Elder 1934) It was also found by Wendt (1934) Harris (1943) Behar et al (1965) and Stebbins et al (1966) In addition it appears in the cochlear microphonic of rhesus monkeys (Vernon 1967) Thus it is surprising that it did not appear in the present series of monkeys This failure to find the 4 kHz dip is parallel to the results of a

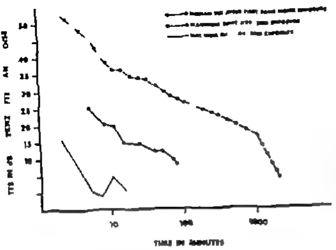

Fig. 1. Recovery from temporary threshold shift after exposure to 12 min of tape recorded tank noise. The median shift seen in nine monkeys after the first exposure to this noise (solid line) is compared with the largest shift (M 39 dashed lines) and the smallest shift (M-4 dotted lines) seen after the second exposure.

recent study of lemur hearing (Mitchell et al 1970) Three lemurs showed the dip three lemurs did not. Neither sex nor age nor species could account for the difference Other studies in which the 4 kHz dip did not occur are Semenoff & Young (1964) and Fujita & Elliott (1965)

Recovery after exposure to tank noise

The 12 min exposure to the tape recorded tank noise was relatively innocuous In fact the TTS was too transient to permit adequate testing at more than one frequency The frequency chosen was 2 kHz.

It was impossible to obtain measures of TTS at exact prearranged intervals of time However each subject s recovery was monitored carefully enough to allow adequate interpolations for statistical comparisons. Such a comparison is given in Fig. 1 which contains a recovery function based on the median TTS of nine subjects (solid lines). Because of missing data, the function is only defined between 5 and 80 min after exposure Over this range the recovery is a logarithmic function of time after exposure

The median statistic is an adequate reflection of individual data With one notable exception all subjects showed a logarithmic recovery The one exception, M-43 showed a delayed recovery a type previously described by Ward

Both the largest and the smallest individual records of TTS were seen after the second exposure to the noise These records are also shown in Fig. 1 The animal with the least TTS M-4 had shown the second to the largest amount of TTS after his first exposure In contrast, M 39 who had shown the least TTS_2 after the first exposure had the most TTS after the second exposure

Most of the subjects (seven out of nine) showed less TTS_2 after the second exposure than after the first. This drop in measured TTS was not the result of an increase in the pre-exposure threshold between the first and second exposure. If anything sensitivity at 2 kHz had improved (mean thresholds of 7 dB and 3 dB SPL, respectively). The group correlation between TTS on the first and second exposures was negative (−0 74)

Recovery after exposure to the two-impulse condition

In the preceding section the TTS following exposure to tank noise was shown to recover as a linear function of the logarithm of time. This relation was expected, since it had been shown to occur for animals as diverse as man (Ward et al 1958) cat (Miller et al. 1963) chinchilla (Peters 1965) rat and monkey

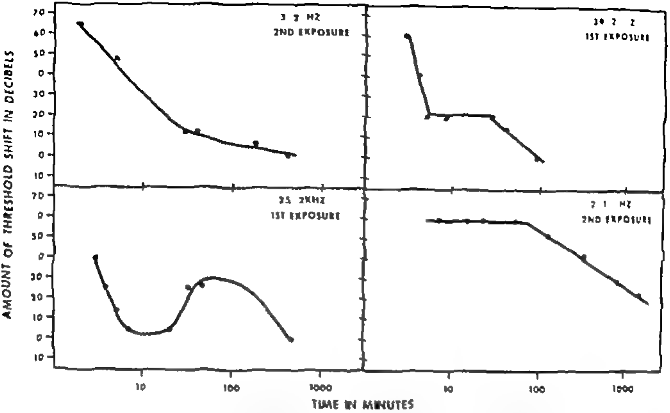

Fig. 2. Curves of recovery from TTS seen in the rhesus monkey after exposure to impulse noise. A logarithmic recovery was shown at kHz for M 3 after the second impulse exposure. A rebound recovery was shown at kHz by M 5 after her only impulse exposure. A diphasic recovery was shown at kHz by M 39 after the first impulse exposure. A delayed recovery was shown by M at 14 kHz after his second impulse exposure. Other examples from different subjects in the same experiment may be found in Luz and Hodge (1971).

(Harris 1967). A log-linear function was also expected to follow the monkey's exposure to impulse noise, and it did. In addition, several other types of recovery were noted.

These non logarithmic functions ("rebound", "diphasic recovery" and "plateau") have also been found in humans exposed to high levels of gunfire (Luz & Hodge 1971). Schematic examples of the four types of recovery functions may be found in that report. Actual examples, taken from the subjects of the present study, are shown in Fig. 2. Additional records from these same monkeys may also be found in Luz & Hodge.

The presence of these different types of recovery functions is also reflected in the group statistics. In Fig. 3, median values of TTS are given over the intervals of 5 to 480 min of 2 kHz and 15 to 480 min for 8 and 14 kHz. Although the median values followed a logarithmic recovery at 2 kHz, they reflected a "rebound" recovery at the higher frequencies of 8 and 14 kHz. Because one subject showed evidence of PTS after the first exposure to impulse noise, only the values from the first exposure were used in Fig. 3.

After each impulse noise exposure, a subject was allowed a recovery period of about four weeks. Two subjects did not recover to within 10 dB of their pre-exposure thresholds during this period. The TTS remaining at that time was called PTS. Subject M 2 suffered a PTS at 14 kHz of 15 dB after the first impulse exposure, and M-4 suffered a PTS of 35 dB at 8 kHz after the second impulse exposure. Some of the other subjects suffered insignificant amounts of PTS, in the order of 5 to 10 dB. At the end of five TTS exposures the mean loss for the nine subjects was 0 dB, 3 dB, 4 dB and 9 dB at 1, 2, 8 and 14 kHz respectively.

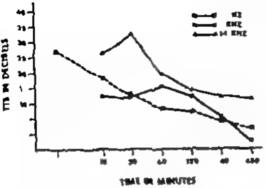

Fig. 3. Median values of TTS for nine monkeys after the first exposure to tw... impulses. Values are defined at 2 kHz beginning at 5 min. For 8 and 14 kHz, values begin at 15 min. For the frequency showing the most enduring TTS (14 kHz), only two monkeys had not recovered to within 10 dB of pre-exposure threshold at 16 hr after the exposure.

The course of recovery at the six test frequencies is shown in Fig. 4, which is based on the median values of threshold shift found after the maximum exposure for each monkey. The reference thresholds (zero shift) are the thresholds determined immediately before the exposure to the ten impulse conditions.

The median threshold shift was greatest at 8 or 10 kHz during the first eight days, at 10 or 14 kHz for the next 4 days and at 14 kHz at the sixty-fourth day. This change in the maximum threshold shift may also be seen in Fig. 5, which shows the amount of shift as a function of frequency for each of the seven test days.

The rapid drop in median shift at 8 kHz between eight and 16 days was mainly due to one animal (M-64). His recovery at 8 kHz was a linear rather than a logarithmic function of days after exposure. Although this linear recovery was not common, it did occur in other animals. Examples for M-49 at 1 kHz, M 3 at 4 kHz, M-64 at 8 kHz, and M-47 at 14 kHz are given in Fig. 6. There also appeared to be some "hybrid" recovery functions: recoveries that were linear in time and then logarithmic in time.

At the end of 64 days, the final audiogram was determined for each subject. An audio-

Threshold shift after ten and twenty impulse conditions

Following the recovery period for the last exposure to tank noise, all monkeys were exposed to ten successive impulses. The amount of threshold shift was determined for 1, 2, 4, 8, 10 and 14 kHz at 24 hr, 2, 4, 8, 16 and 32 days following exposure. The two most resistant monkeys (M-47 and M-49) recovered within a few days of the exposure and were subsequently exposed to 20 additional impulses.

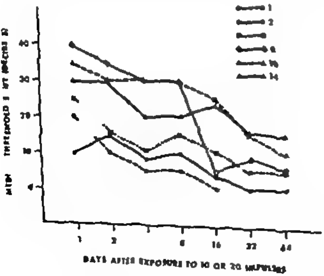

Fig. 4. Median amount of threshold shift found at 1, 2, 4, 8, 16, 32, and 64 days after the maximum exposure to impulse noise received by each of the nine monkeys. The reference thresholds (0 dB) are those found immediately before the exposure to the 10 or 20 impulses.

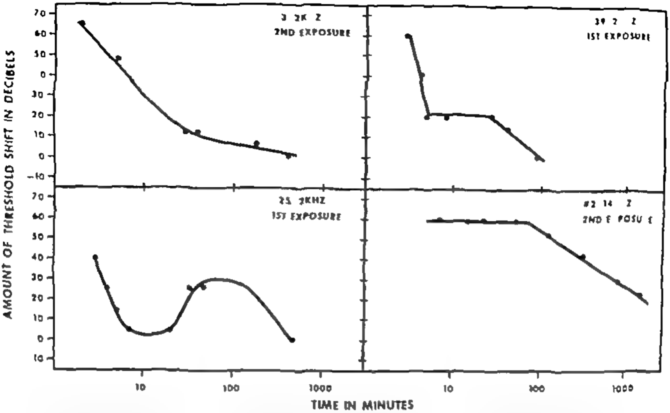

Fig 2 Curves of recovery from TTS seen in the rhesus monkey *after exposure to impulse noise A logarithmic* recovery was shown at kHz for M 3 after the second impulse exposure A rebound recovery was shown at 2 kHz by M 25 after her only impulse exposure A diphasic recovery was shown at kHz by M-39 after *the first impulse exposure A delayed* recovery was shown by M 2 at 14 kHz after his second impulse exposure Other examples from different subjects in the same experiment may be found in Luz and Hodge (1971)

(Harris 1967) A log linear function was also expected to follow the monkey s exposure to impulse noise and it did In addition several other types of recovery were noted

These non logarithmic functions (rebound diphasic recovery and plateau) have also been found in humans exposed to high levels of gunfire (Luz & Hodge 1971) Schematic examples of the four types *of recovery functions may be found in that re*port Actual examples taken from the subjects of the present study are shown in Fig 2 Additional records from these same monkeys may also be found in Luz & Hodge

The presence of these different types of recovery functions is also reflected in the group statistics In Fig 3 median values *of TTS* are given over the intervals of 5 to 480 min of 2 kHz and 15 to 480 min for 8 and 14 kHz. Although the median values followed a logarithmic recovery at 2 kHz, they reflected a rebound recovery at the higher frequencies of 8 and 14 kHz. Because one subject showed evidence of PTS after the first exposure to impulse noise only the values from the first exposure were used in Fig 3

After each impulse noise exposure a subject was allowed a recovery period of about four weeks Two subjects did not recover to within 10 dB of their pre-exposure thresholds *during this period The TTS remaining at that* time was called PTS Subject M 2 suffered a PTS at 14 kHz of 15 dB after the first impulse exposure and M-4 suffered a PTS of 35 dB at 8 kHz after the second impulse exposure Some of the other subjects suffered insignificant amounts of PTS in the order of 5 to *10 dB At the end of five TTS exposures* the mean loss for the nine subjects was [illegible] dB 3 dB 4 dB and 9 dB at 1 2 [illegible] and 14 kHz, respectively

TTS recovery vs PTS profiles of TTS vs profiles of PTS etc. No meaningful relations could be established

DISCUSSION

No significant correlation was found between the TTS produced from an initial exposure to two impulses and the PTS seen at 64 days after exposure to ten impulses. For example M-49 and M 39 showed an average TTS of 15 dB and 14 dB respectively for ? 8 and 14 kHz at 30 min after initial exposure. However M-49 suffered the least PTS of any monkey while M 39 suffered the largest dip in its audiogram. The final audiogram of M 39 was most similar to that of M-4 the monkey with the largest amount of TTS after the initial exposure

Although a large amount of TTS did not predict a large amount of PTS it did predict the early development of PTS Only two animals (M 2 M-4) showed a TTS_{30} as great as 50 dB (at any frequency) after the first exposure These same two animals were the only ones to show a PTS as much as 20 dB (at any frequency) after recovery from the second exposure. Following the third impulse exposure a third monkey showed a loss of 20 dB and following the 10 impulse exposure six of the nine normal monkeys showed a PTS of as much as 20 dB at any frequency

Other significant correlations were either trivial or unexpected The correlations between TTS at different frequencies (Table II) were comparable to those found for humans exposed to the same impulse noise source (Fletcher & Loeb 1965) The negative correlation (p (0 05) seen after the first and second exposure to tank noise was unexpected Evidently the characteristics of these ears were being changed during the process of repeated exposures Also unexpected was the association of non-logarithmic recovery patterns with impulse noise exposure. These non-logarithmic recovery patterns appeared to be qualitatively related to susceptibility This was

Table II *Intercorrelations between the amount of TTS seen in each subject at 30 min after the first impulse exposure at the test frequencies of 1 2 8 and 14 kHz and the mean amount of PTS at 8 10 and 14 kHz seen in that subject after the maximal exposure as given above the diagonal*

Analogous correlations for TTS at 120 min are given below the diagonal (For two-tailed test and seven degrees of freedom, **means significance at the 0 01 probability level and t the 0 02 level)

a weak relationship and was most apparent following recovery from the third impulse exposure At that time each of the three monkeys showing 20 dB PTS at any frequency had also shown a rebound at 2 kHz after each of the three 2-impulse exposures For those six monkeys showing less PTS a rebound was detected at 2 kHz in only five of 17 recovery records

The rhesus monkey appears to be more susceptible than man to impulse noise. The comparative data may be found in past reports from this laboratory (Fletcher & Loeb 1965 Fletcher & Loeb 1967 Fletcher 1969). These reports describe the levels of TTS sustained by dozens of volunteers who were exposed to the same impulse source as used in the present study In one study (Loeb & Fletcher 1968) the median subject required over 20 of these impulses to reach a TTS_2 of 30 dB at any frequency None of the human subjects have failed to recover from exposure to these impulses.

The monkeys were also more susceptible to the continuous noise than human subjects, having been exposed to the same tank noise as were some volunteers from a concurrent study The young men demonstrated a median

TTS of 26 dB for 2 kHz at 90 sec after exposure. This figure is almost equal to the median shift at 2 kHz found among the monkeys at 5 min after the equivalent exposure.

Another difference in susceptibility between monkey and human was observed in this study—a *difference in patterns of PTS*. When human hearing is damaged by impulse noise, three classes of pure tone audiograms are found: dips (typically at 4 kHz), divided dips, and abrupt high frequency losses (Salmivalli 1967). In Salmivalli's study of acoustic trauma among Finnish soldiers, 75% showed a dip, 11% a divided dip, and 14% an abrupt loss. In the present study, only two of the nine monkeys showed a well defined dip (M-4 and M-39). For the other seven, the loss was maximal at the highest frequency tested, 14 kHz. (Two of these seven, M-34 and M-47, appeared to have a 'divided dip', but the evidence is equivocal on this point.) Too little is known of the anatomy of the monkey ear to permit an interpretation of these differences between man and monkey. However, it is tempting to relate these differences to the differences between the minimum audible fields of man and rhesus. The rhesus is less sensitive than man below 4 kHz but is sensitive to frequencies at an octave above man's upper limit (Behar, Cronholm & Loeb 1965).

Two unexpected changes occurred in the sensitivity at 1 and 2 kHz. First, there was an apparent increase in sensitivity at these frequencies after the loss of higher frequency hearing. Second, there was a decrease in susceptibility to TTS at these frequencies.

The increase in sensitivity at 1 kHz was found in seven of the nine monkeys. It was also found in the abnormal subject, M-25. Only three of the monkeys showed an improvement at 2 kHz (M-4, M-2, and M-49). Such an increase of sensitivity to low frequency tones is thought to follow destruction of more basal hair cells and has been ascribed to a decrease in the lateral inhibition exerted by one set of neurons on another set (Carterette 1969). Since Carterette has cited many examples of this phenomenon, it seems reasonable that a real change in sensitivity could have occurred in the present study. However, the evidence should be interpreted with caution, since there was no control group in the experimental design.

During the course of the three '2-impulse' exposures and the two tank noise exposures, a resistance to TTS appeared in the low frequencies, 1 and 2 kHz. This resistance was demonstrated in two ways: (i) By comparison of the highest absolute thresholds observed at 20 or more minutes after the first and third exposure to the '2 impulse' condition. (ii) By comparison of TTS_4 at 2 kHz after the first and second exposure to tank noise. Out of nine monkeys, eight showed less absolute shift at 1 kHz after the third '2-impulse' exposure than after the first. At 2 kHz, five out of nine showed less shift. In contrast, at 8 and 14 kHz, six out of nine showed *more* absolute shift between these two exposures. An increased tolerance to low frequency noise was demonstrated when seven out of nine monkeys showed less TTS_2 after their second exposure to tank noise than after their first. This increased tolerance cannot be attributed to a decrease in sensitivity at 2 kHz, for, if anything, sensitivity had increased at this frequency.

A similar increase in resistance to noise was reported for the rhesus and impulse noise by Romba & Gates (1964) and for cats and continuous noise by Miller et al. (1963). In addition, there are at least four reports in which decreases in TTS occurred for humans (Murray & Reid 1946, Coles 1967, Loeb & Fletcher 1963, Ward 1970). Each of these reports involved hazardous exposures—impulses (Murray and Reid, Coles) and high intensity intermittent noise (Loeb & Fletcher, Ward). The noises used in all four studies have four features in common: (i) They produce high levels of TTS. (ii) They sometimes produce aberrant (non-logarithmic) recovery functions. (iii) The variance in TTS between

subjects is typically greater than for continuous noise (iv) They often produce a phase of supranormal excitability" (Murray & Reid 1946) at some test frequencies (Ward 1970· Hodge & McCommons 1966) Although increased resistance to noise is not invariably found after this type of exposure it may occur often enough to account for the popular belief in toughening ears a superstition shared by many workers in high noise environments

TTS of 26 dB for 2 kHz at 90 sec after exposure This figure is almost equal to the median shift at 2 kHz found among the monkeys at 5 min after the equivalent exposure

Another difference in susceptibility between monkey and human was observed in this study—a difference in patterns of PTS When human hearing is damaged by impulse noise three classes of pure tone audiograms are found dips (typically at 4 kHz) divided dips and abrupt high frequency losses (Salmivalli 1967) In Salmivalli s study of acoustic trauma among Finnish soldiers 75 % showed a dip 11% a divided dip and 14% an abrupt loss In the present study only two of the nine monkeys showed a well defined dip (M-4 and M 39) For the other seven the loss was maximal at the highest frequency tested 14 kHz (Two of these seven M 34 and M-47 appeared to have a divided dip but the evidence is equivocal on this point) Too little is known of the anatomy of the monkey ear to permit an interpretation of these differences between man and monkey However it is tempting to relate these differences to the differences between the minimum audible fields of man and rhesus The rhesus is less sensitive than man below 4 kHz but is sensitive to frequencies at an octave above man s upper limit (Behar Cronholm & Loeb 1965)

Cochlear Pathology in Monkeys Exposed to Impulse Noise

by Valdemar M Jordan [1] Marilyn L Pinheiro [1] Kazuo Chiba [1] and Armando Jimenez[1]

INTRODUCTION

Many humans both in military and civilian life are subject to exposure to the intense pressure waves of impulse noise Early reports on cochlear damage due to this type of acoustic trauma were made by Hamberger & Hyden (1945) on guinea pigs by Perlman (1948) on rabbits and by Lindquist Neff & Schuknecht (1954) on cats These investigators used decalcification and serial sectioning to prepare their specimens Recently improved methods of histological preparations have made it possible to carry out more accurate and detailed evaluations of cochlear structure

By using the surface preparation technique histologists have been able to compare the patterns of hair cell damage induced by differently shaped impulses Poche Stockwell & Ades (1969) used the surface preparation technique to explore hair cell destruction in guinea pigs after exposure to cap gun fire Also in the guinea pig Hamernik Henderson Dosanjh & Sitler (1971) studied the effects of impulses generated by a shock tube and by an exploding wire Together with the sonic boom study of Majeau-Chargois Berlin & Whitehouse (1967) these studies form a valuable intraspecies comparison

A different approach to the study of impulse noise is the interspecies comparison the approach of the present study Rhesus monkeys were deafened by exposure to a spark gap impulse This impulse had been previously used in several studies with humans (Loeb & Fletcher 1968 Fletcher 1969 Fletcher & Loeb 1965 Fletcher & Loeb 1967) and in one study with chinchillas (Luz & Mosko 1971)

METHOD

Subjects

The left ears of ten rhesus macaque monkeys had been exposed to impulses (The one abnormal subject M 25 omitted from most analyses in the previous report was included) Total exposures ranged from two impulses for M 25 through 16 impulses for M ? M-4 M 30 M 39 M-40 and M-64 and to 36 impulses for M-47 and M-49 These figures represent multiple exposures ranging up to four months Subjects were studied at least three months after the last exposure

Preparation

In order to avoid confusion between post mortem changes (Jordan et al) and pathological lesions the monkey ears were fixed in vivo using general anesthesia and the principles of mastoid surgery The animals were anesthetized by intramuscular injection of serylan (0 5–1 0 mg/kg of body weight) and by subcutaneous atropine sulfate (0 0? mg/lb of body weight) The left ear was prepared and draped in the usual surgical manner The overlying soft tissue was rapidly removed by sharp and blunt dissection Under the dissecting microscope cutting burrs were used to

[1] Case Western Reserve University Medical School Cleveland Ohio 44106 USA
In conducting the research described in this report the investigators adhered to the Guide for Laboratory Animal Facilities and Care as promulgated by the Committee on the Guide for Laboratory Animal Resources National Academy of Sciences—National Research Council

penetrate the cortex at Henle's spine. The mastoid antrum was located first and then a simple mastoid cavity was created. The posterior canal wall and the lateral wall of the attic were removed to provide good exposure of the tympanic membrane. By sharp dissection with suitable elevators the ear drum was lifted out of the annulus to expose the incudostapedial joint. This was carefully separated so that as the drum was turned forward, it carried the attached malleus and incus with it. In this manner excellent visualization of the medial wall of the middle ear was obtained. All essential structures could be identified easily.

Actual fixation of the inner ear was carried out in the following manner. The round window membrane was carefully punctured by a microscopic right-angle pick. Next, the stapes with its footplate was extracted from the oval window. Then micropipettes were used to perfuse the fixative solution (paraformaldehyde containing 0.5% glutaraldehyde with a pH of 7.4) through the round window opening into the scala tympani. Gentle perfusion was continued until the fixative could be seen welling out of the oval window. This procedure was repeated over a five minute period to be certain that as much perilymph as possible had been replaced by the fixative. Finally each window was sealed with dental wax.

The dorsum of the skull was then exposed. A central opening in the bone was made with a Stryker temporal bone saw. This was rapidly enlarged with rongeurs until it was possible to enucleate the brain sacrificing the animal. The left temporal bone was immediately removed using the Stryker saw in the manner reported by Schuknecht (1968). The bone plug was reinfused at once with the paraformaldehyde according to the method described above. The windows were left open, and the specimen was immersed in the fixative for a minimum of twenty-four hours. The inner ears were later stained with buffered osmic acid solution (0.5%) using the same procedure as for fixation. The stain was left sealed in the perilymphatic spaces for 30 min. The cochlea was then flushed thoroughly with 70% ethanol in which it was immersed until cochlear dissection could be performed.

Dissection

Microdissection and surface preparations were used to study the 10 monkey cochleae. This method, originally used by Retzius (1882, 1884), was revived and revised by Engstrom, Ades & Hawkins (1964) who have adequately described the procedures followed in this investigation. Through the use of this method individual hair cells could be counted and percentages of losses accurately plotted against the distance from the basal end of the basilar membrane. The nerve fibers could be easily observed. Thus complete histological data could be made available for comparison with the clinical findings on the experimental animals.

Before beginning exposure of the cochlea each window was resealed with dental wax to prevent the scalae from being contaminated with bone dust. Under the Zeiss binocular microscope and a 70% alcohol drip the labyrinthine bone was rapidly removed with a high speed dental drill. As the overlying bone was thinned the membranous inner ear was easily recognized because of the dark osmic acid stain. Thus the contour of the cochlea and the semicircular canals could be followed in the drilling. Correct shaping of the bony cochlear coils was essential in order to facilitate the later removal of the basilar membrane and its superstructure. When the bony labyrinthine covering had been made eggshell thin the specimen was again immersed in 70% ethanol and examined under the stereomicroscope. Special dental picks were used to flick away carefully the thinned soft residual bony shell uncapping the cochlea. After removing the spiral ligament, the stria vascularis, Reissner's membrane and the tectorial membrane, the entire length of the cochlea from cecum ves-

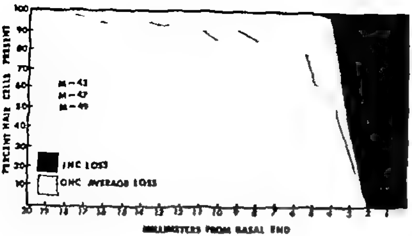

Fig 7 Group I Averaged hair cell loss for M-43 M-47 and M-49 Outer hair cell loss overlaps all inner hair cell loss

tibulare (hook) to helicotrema could be observed Under low power magnification it was possible to estimate the extent and location of damage to the organ of Corti and myelinated nerve fiber bundles Phase contrast microscopy was used for studying the finer dealls of cytoarchitecture

The length of the basilar membrane from its basal end in the hook area to its apical termination was carefully measured along the inner hair cells by means of a calibrated optical scale under 400X magnification. The basilar membranes of the 10 monkeys ranged in length from 23 30 mm to 25 80 mm with a mean length of 24 59 mm

Both inner and outer hair cells were counted in each cochlea Their exact locations were plotted on cochleograms A sensory cell was considered present if it could be observed even though it might appear abnormal in some way—i e pulled away from pillar cells swollen or with stereocilia absent Single or small groups of missing hair cells were counted by the phalangeal scars which replaced them The number of hair cells missing in a destroyed segment could be estimated from the average number of hair cells in normal adjacent segments of the same length Some fourth row outer hair cells were observed but these were not documented because there was no regularity to their presence The percentage of hair cells in each row was calculated from the cochleograms for every half millimeter along the basilar membrane These percentages were used to plot graphs of the damage

RESULTS

The most obvious result of this study was the great variability in extent and severity of cochlear damage The cochleae studied seemed to fall into three distinct groups

Group I (M-43 M-47 and M-49) showed the least damage (Fig 7 also Fig 23) Each had an area of destruction along the initial two to three millimeters of the basilar membrane in the hook area. Here both the myelinated nerve fibers and the organ of Corti had been totally destroyed Some thin flat epithelial cells were observed paving the basilar membrane Beyond this damaged area myelinated radial nerve fiber bundles crossing the osseus spiral lamina appeared abruptly (Fig. 8) In M-43 and M-47 the nerve fibers remained dense throughout the length of the cochlear coils In M-49 normal nerve fiber density was interrupted twice in the basal turn by narrow wedges of missing fibers (Fig. 9) The organ of Corti opposite these missing fibers was normal

The structure of the organ of Corti itself took shape on the basilar membrane opposite the beginning of the appearance of the nerve fibers Inner hair cells were observed first and reached a full complement within less than a millimeter Throughout the remainder of the

RESULTS

The most obvious result of this study was the great variability in extent and severity of cochlear damage The cochleae studied seemed to fall into three distinct groups

Group I (M-43 M-47 and M-49) showed the least damage (Fig 7 also Fig 23) Each had an area of destruction along the initial two to three millimeters of the basilar membrane in the hook area. Here both the myelinated nerve fibers and the organ of Corti had been totally destroyed. Some thin flat epithelial cells were observed paving the basilar membrane Beyond this damaged area myelinated radial nerve fiber bundles crossing the osseus spiral lamina appeared abruptly (Fig. 8) In M-43 and M-47 the nerve fibers remained dense throughout the length of the cochlear coils In M-49 normal nerve fiber density was interrupted twice in the basal turn by narrow wedges of missing fibers (Fig. 9) The organ of Corti opposite these missing fibers was normal

The structure of the organ of Corti itself took shape on the basilar membrane opposite the beginning of the appearance of the nerve fibers Inner hair cells were observed first and reached a full complement within less than a millimeter Throughout the remainder of the

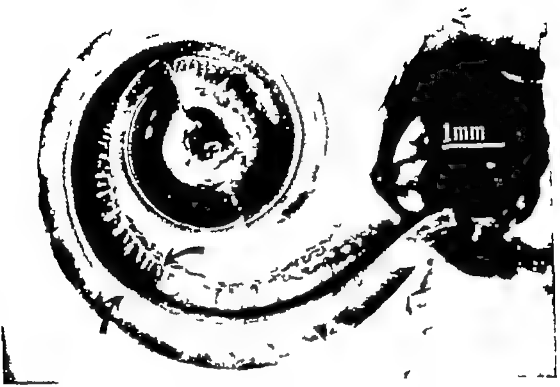

Fig. 11. M-25. Extensive destruction hook area and lower basal turn. Note abrupt beginning of myelinated nerve fibers followed by appearance of organ of Corti (×12).

tion of cochlear damage with variations only in degree of severity and extent along the basilar membrane. Hook area damage was limited to two to three millimeters of depleted myelinated nerve fibers and organ of Corti destruction. As soon as the darkly stained nerve bundles became dense, the cytoarchitecture of the organ of Corti was rapidly reorganized. Inner hair cells appeared first, and outer hair cells followed closely. At about 4.0 mm from the basal end of these cochleae the population of sensory cells had reached near-normal percentages. Myelinated radial nerve fiber bundles showed normal density. In M-4, M-30, M-39 and M-64, a longitudinal separation between Hensen's cells and Deiters' cells was observed to extend for several millimeters along the lower half of the basal turn (Fig. 12). At 5.0 mm to 6.0 mm from the basal end, a precipitous outer hair cell loss occurred. The peak of this damage was located at 8.0 mm to 9.0 mm along the basilar membrane. In both M-4 and M-64 two narrow wedges of missing radial nerve fibers paralleled areas of complete disruption of the organ of Corti (Figs. 13 and 14). A slight loss of inner hair cells accompanied severe outer hair cell loss at 6.0 mm to 7.0 mm from the basal end in M-39 and M-64. M-4 had a more extensive inner hair cell loss in the region from 9.0 mm to 12.0 mm along the basilar membrane. These inner hair cell losses occurred only in areas where the organ of Corti itself was totally disrupted. Inner hair cells were usually present where the structure was partially intact. In some areas, where outer hair

cochlea the inner hair cells were normal in all three animals in this group. Outer hair cells appeared soon after inner hair cells with the innermost row 1 observed first, followed by rows 2 and 3. All three rows rapidly increased to a near normal population. In M-43 and M-47 there were two areas of outer hair cell loss further along the basilar membranes. Both animals had outer hair cells missing at 8.0 mm to 9.0 mm from the basal end. These losses were more marked for the third outermost row. Rows 1 and 2 had only slight losses in the same regions. M-43 had a second wedge of absent outer hair cells at 10.0 mm to 11.0 mm. M-47 had a peak of third row outer hair cell loss at 15.0 mm to 16.0 mm with the damage to the row extending further basalward than toward the apex. M-49 was the cochlea most resistant to the noise trauma. It was found to be different from the other cochleae—i.e. the first row of outer hair cells showed the greater damage throughout the lower half of the basal turn with a peak of 15% loss at 8.0 to 9.0 mm. In the upper half of the basal turn the third row had more phalangeal scars, indicating small regions of missing cells.

In Group I only M-47 was observed to have a longitudinal split between Hensen's cells and Deiters' cells in the lower section of the basal coil.

Group II (M 3 and M 25) had the greatest extent of complete destruction of organ of Corti and myelinated nerve fibers in the hook area and lower portion of the basal turn. In both cochleae this damage extended along the basilar membrane for about seven millimeters (Figs. 10, 26). At this point the myelinated radial nerve fiber bundles appeared abruptly and the structure of the organ of Corti took shape (Fig. 11). Inner hair cells appeared suddenly. In M 25 these increased to a full complement within a half millimeter. In M 3 90% of inner hair cells were present in a half millimeter with only occasional cells missing along the next few millimeters of the basilar membrane.

In both M 3 and M 25, the outer hair cells appeared shortly after the inner hair cells. These increased gradually throughout the basal turn, reaching a normal population in the lower half of the middle coil. The outermost row of sensory cells was observed to be most damaged while the innermost row was least damaged. Row 2 was only slightly more involved than row 1 and much less so than row 3. Row 3 in both animals showed at least two areas where the gradual increase in the outer hair cell population was briefly reversed. These foci of greater third row hair cell loss were marked by scarring of the reticular lamina. Losses peaked at 11.5 mm and 13.0 mm in M 3 and at 14.0 mm and 16.0 mm in M 25. Beyond 18.0 mm from the basal end these cochleae were normal in appearance.

Group III included half the inner ears in this study. M 2, M-4, M 30, M 39 and M-64 demonstrated basically the same configura-

cochlea the inner hair cells were normal in all three animals in this group Outer hair cells appeared soon after inner hair cells with the innermost row 1 observed first followed by rows 2 and 3 All three rows rapidly increased to a near normal population In M-43 and M-47 there were two areas of outer hair *cell loss further along the basilar membranes* Both animals had outer hair cells missing at *8 0 mm to 9 0 mm from the basal end* These losses were more marked for the third outer most row Rows 1 and 2 had only slight losses in the same regions M-43 had a second wedge of absent outer hair cells at 10 0 mm to 11 0 *mm* M-47 *had a peak of third row outer hair* cell loss at 15 0 mm to 16 0 mm with the damage to the row extending further basal ward than toward the apex M-49 was the cochlea most resistant to the noise trauma It was found to be different from the other cochleae—i e the first row of outer hair *cells showed the greater damage throughout* the lower half of the basal turn with a peak of *15% loss at 8 0 to 9 0 mm In the upper* half of the basal turn the third row had more phalangeal scars indicating small regions of missing cells

In Group I only M-47 was observed to have a longitudinal split between Hensen s cells and Deiters cells in the lower section of the basal coil

Group II (M 3 and M 25) had the greatest extent *of complete destruction of organ of* Corti and myelinated nerve fibers in the hook area and lower portion of the basal turn In both cochleae this damage extended along the basilar membrane for about seven millimeters (Figs 10 26) At this point the myelinated radial nerve fiber bundles appeared abruptly *and the structure of the organ of Corti took* shape (Fig 11) Inner hair cells appeared suddenly *In M 25* these increased to a full complement within a half millimeter In M 3 *90% of inner hair cells* were present in a *half* millimeter with only occasional cells missing along the next few millimeters of the basilar membrane

In both M 3 and M 25 the outer hair cells *appeared shortly after the inner hair cells* These increased gradually throughout the ba sal turn reaching a normal population in the lower half of the middle coil The outermost row of sensory cells was observed to be most damaged while the innermost row was least damaged Row 2 was only slightly more involved than row 1 and much less so than row 3 *Row 3 in both animals showed at least two areas where the gradual increase* in the outer hair cell population was briefly reversed These foci of greater third row *hair cell loss* were marked by scarring of the reticular la mina Losses peaked at 11 5 mm and 13 0 mm in M 3 and at 14 0 mm and 16 0 mm in M 25 Beyond 18 0 mm from the basal end these cochleae were normal in appearance

Group III included half the inner ears in *this study* M 2 M-4 M 30 M 39 and M-64 demonstrated basically the same configura

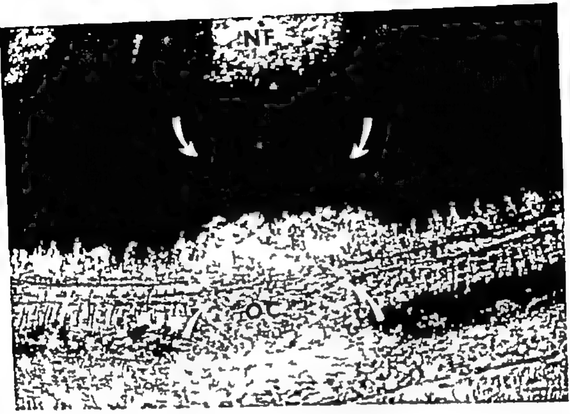

Fig 14 M-4 Close-up of missing wedge of myelinated radial nerve fibers opposite disrupted organ of Corti (×200) NF=missing nerve fibers, OC=missing organ of Corti

cells were entirely absent, the reticular lamina remained Except for the missing wedges of nerve fibers described above myelinated radial nerve bundles appeared normal throughout the cochleae beyond the hook area.

Beyond 10 0 mm along the basilar membrane these inner ears showed a gradual restoration of outer hair cell population. Almost all outer hair cells were present in the apical half of the middle coil Occasional degenerated cells were replaced by phalangeal scars on the reticular lamina Scars were formed where outer hair cells were destroyed The phalangeal processes of the supporting cells grew together at the reticular lamina to maintain its contiguity

Group III could be subdivided according to severity and extent of hair cell destruction. M-4 and M 39 were the most severely damaged ears in this group with the greater portion of the basal turn of both cochleae disrupted (Figs 15 29) Although M 2, M 30 and M-64 had similar configurations of damage the actual percentages of hair cell destruction and the extent of the basilar membrane involved were more circumscribed (Figs 16 27 31) In M-4 and M 39 damage was often most severe to the first row of outer hair cells in places where the overall destruction was at its greatest from 6 0 mm to 10 0 mm along the basilar membrane In contrast the third row of outer hair cells in M 2, M 30 and M-64 was usually the row to have suffered the greatest losses

In all three groups of monkey inner ears the sensory cells immediately adjacent to regions of damage often appeared abnormal or swollen even though they had not degenerated Some were displaced from their normal regular arrangement in even rows The stereocilia were missing entirely from some outer hair cells and were either distorted or partially

cells were entirely absent the reticular lamina remained. Except for the missing wedges of nerve fibers described above, myelinated radial nerve bundles appeared normal throughout the cochleae beyond the hook area.

Beyond 10.0 mm along the basilar membrane these inner ears showed a gradual restoration of outer hair cell population. Almost all outer hair cells were present in the apical half of the middle coil. Occasional degenerated cells were replaced by phalangeal scars on the reticular lamina. Scars were formed where outer hair cells were destroyed. The phalangeal processes of the supporting cells grew together at the reticular lamina to maintain its contiguity.

Group III could be subdivided according to severity and extent of hair cell destruction. M-4 and M-39 were the most severely damaged ears in this group with the greater portion of the basal turn of both cochleae disrupted (Figs. 15–29). Although M-2, M-30 and M-64 had similar configurations of damage, the actual percentages of hair cell destruction and the extent of the basilar membrane involved were more circumscribed (Figs. 16, 27, 31). In M-4 and M-39 damage was often most severe to the first row of outer hair cells in places where the overall destruction was at its greatest from 6.0 mm to 10.0 mm along the basilar membrane. In contrast the third row of outer hair cells in M-2, M-30 and M-64 was usually the row to have suffered the greatest losses.

In all three groups of monkey inner ears the sensory cells immediately adjacent to regions of damage often appeared abnormal or swollen, even though they had not degenerated. Some were displaced from their normal regular arrangement in even rows. The stereocilia were missing entirely from some outer hair cells and were either distorted or partially

absent on others The finer deails of intracellular changes remain to be determined by electron microscopy

In all the cochleae both radially and spirally running non myelinated nerve fibers (Fig 17) could be observed in the tunnel of Corti Since these seemed to have no regular arrangement it was impossible to judge whether they were depleted in areas of significant outer hair cell loss

Some abnormality was observed in Reissner s membrane in all animals Large rounded osmiophilic cell like clumps of material appeared on the endolymphatic surface of the membranes (Fig 18 A) Dark filaments seemed to protrude from these formations In some areas it was possible to observe the darkly stained clusters of material coming together (Fig 18 B) Other areas disclosed occasional groups of the dark strands or filaments apparently gravitating toward each other (Fig 18 C)

DISCUSSION

The great variability in the sensitivity of the cochlea to acoustic trauma has been noted previously in histological investigations of animal ears (Poche Stockwell & Ades 1969 Stockwell Ades & Engström 1969) Similarly the monkey cochleae showed a wide range in the severity and extent of destruction However certain over all patterns and characteristics of damage emerged

All of the cochleae had some damage in the cecum vestibulare at the beginning of the basilar membrane near the location of the round and oval windows This varied in ex

tent from two to seven millimeters along the membrane and *involved destruction of both* the organ of Corti and the myelinated nerve fibers This held true even for animals with *minimal* degeneration in other areas

In contrast other investigators studying impulse noise have observed no degeneration in this region or degeneration only associated with extensive damage in the more medial regions (Lindquist Neff & Schuknecht 1954 Schuknecht & Tonndorf 1953 Poche Stockwell & Ades 1969 Majeau-Chargois Berlin & Whitehouse 1967 Hamernick Henderson Dosanjh & Sitler 1971) The reason for this difference is obscure but three observations may be relevant (i) The cochlea of man seems to be more susceptible to damage in the base than in more medial areas (Bredberg 1968) Perhaps the monkey shares this characteristic (ii) The peak pressure of this impulse was larger than that reported in *other studies* Under *some circumstances* the area of maximal damage moves basalward with increased intensity of exposure (Stockwell *Ades & Engström 1969) (iii) The con* densation of the impulse was fairly short (60 μsec) For the guinea pig shorter impulses seem to be associated with more damage in the base than longer impulses (Hamernick Henderson Dosanjh & Sitler 1971)

Another common feature was a second region of susceptibility at 8 0 to 10 0 mm along the basilar membrane in the basal turn of the cochlea For two of the animals (M 3 and M 25) this distinction is meaningless since there were no remaining hair cells between the two regions of destruction the first 7 mm of their cochleae were absent In all other animals a small island of less heavily damaged hair cells separated the two regions

Even the minimally involved animals of Group I tended to have sharp peaks of damage in this area In five monkeys (Group III) the damage in this region made a broad notch of destruction This notch was sharply bounded on the basal side by normal organ of Corti On the apical side the change back toward normal was more gradual Lesser *notches of damage in all* animals were always sharply demarcated from normal or near normal organ of Corti (Figs 19 and 20) Abrupt transitions from normal to damaged areas and the sharp localization of such areas have been reported not only for impulse noise (Poche Stockwell & Ades 1969) but also for other types of noise trauma (Stockwell Ades & Engström 1969) The same effect was found in studies of damage due to ototoxic drugs (Stebbins Miller Johnsson & Hawkins 1969) The greater the amount of total hair cell loss the wider the notch of involvement In other words the extent of the damaged area was positively related to the severity of hair cell destruction The sensitivity of the basilar membrane to acoustic trauma at 8 0 mm to 10 0 mm has been pointed out by Schuknecht & Tonndorf (1953) and by Poche Stockwell & Ades (1969) who have studied the effects *of noise on the cochleae of cats and guinea* pigs respectively Bredberg (1968) also noted that this region was subject to degeneration *in the inner ears of humans who had suffered* noise trauma This part of the basilar membrane has been observed to respond maximally to the frequencies between *8 000 Hz* and 4 000 Hz. These are the frequencies at which both temporary and permanent shifts in the threshold of hearing are *audiometrically* recorded when the ear is exposed to intense sound

It would appear that the damage observed in these monkey cochleae was of mechanical origin The shock wave of the impulse initially hit the hook area causing total destruction in this region The main notch of damage at 8 0 mm to 10 0 mm may have coincided with the maximum amplitude of the traveling wave along the cochlear duct with lesser notches distributed in relation to successive peaks of the bulges Békésy (1953) described the vibrations of the cochlea as radial near the base He observed that these changed to longitudinal vibrations at a distance along the basilar membrane determined by the in-

tensity of the stimulus Such a change of vibratory pattern might increase stress on cochlear structures It might be hypothesized that this transition occurred at 8 0 mm to 10 0 mm from the base in these animals

The longitudinal separation between Hensen s cells and Deiters cells was observed in half the cochleae This split extended over several millimeters in the lower turn basal ward to the 8 0 mm to 10 0 mm section It was more extensive in some monkeys than in others A region of less severely damaged organ of Corti usually paralleled this separation although in some cases the third row of outer hair cells had been torn away together with the Hensen s cells Békésy (1953) first described this phenomenon in studies in which he used intense acoustic stimulation Beagley (1965 *a*) also noted it and suggested it served as a protective mechanism Using electron microscopy he found that the Hensen s cells joined Deiters cells only at the reticular lamina (1965 *b*) Below this junction he observed a canal-like intercellular space Beagley thought the Hensen Deiters separation was due to longitudinal stress Békésy has described the shearing forces of the basilar membrane as more longitudinal in the region of the outer hair cells and more radial nearer the inner hair cells (1951) He observed (1953) that the cochlear vibrations began at the Hensen s cells and passed inward to the outer hair cells Certainly the splitting off of the Hensen s cells from Deiters supporting elements is consistent with the complex patterns of vibrations and stresses that have been reported

After initial loss in the hook area and lowermost basal turn the darkly stained myelinated nerve fiber bundles appeared normal with few exceptions This was true even where the organ of Corti was greatly disrupted and in areas where almost all outer hair cells were missing Further absence of nerve fibers was observed in only three monkeys These losses took the shape of narrow wedges with the wider part toward the habenula perforata In two animals (M-4 and M-64) these occurred only where segments of the organ of Corti were completely destroyed However in M-49 two wedge-shaped losses were seen opposite an apparently normal organ of Corti

Inner hair cells seemed to be very resistant to the trauma of impulse noise Poche Stockwell & Ades (1969) also made this observation Inner hair cells were destroyed only in areas where the organ of Corti was totally disrupted In studies of ototoxicity Stebbins Miller Johnsson & Hawkins (1969) found that the relative loss of inner hair cells paralleled and often exceeded the loss of outer hair cells

The reticular lamina also appeared extremely durable It was often intact in areas where all outer hair cells had degenerated The strength of this phalangeal network has been described previously by Stebbins Miller Johnsson & Hawkins (1969) and others The reticular membrane evidently has the capacity to mend itself thus sealing off the endolymph of the scala media from the bodies of the hair cells which are bathed in cortilymph

In this study the radial gradient of involvement of the outer hair cells rows differed from most other reports Poche Stockwell & Ades (1969) observed equal damage to all three rows of outer hair cells in guinea pigs exposed to impulse noise Stockwell Ades & Engström (1969) found that the first row of outer hair cells suffered the greatest destruction in trauma due to intense noise In guinea pigs subject to an intense 500 Hz tone over long periods of time Beagley (1965 *a*) described the damage as decreasing from the first to the third row of outer hair cells In this investigation the third row of outer hair cells was generally the most involved and the first row least (Figs 21 and 22) Bredberg (1968) noted this type of pattern of sensory cell loss in one third of the 41 human cochleae he examined This radial gradient of damage would be consistent with Békésy s observation (1953) that the vibrations of the cochlear structures began with Hensen s cells

The Relationship between Permanent Threshold Shift and the Loss of Hair Cells in Monkeys Exposed to Impulse Noise

by Marilyn Pinheiro Valdemar Jordan and George A Luz

INTRODUCTION

Just a few years after psychologists began using conditioned responses to evaluate hearing in animals the same techniques were employed to study the effects of hazardous noise (Upton 1929 Kemp 1935 Horton 1934) At the same time new developments in histology (Guild 1921) and electrophysiology (Wever & Bray 1930) allowed scientists several different ways of observing damaged ears During the last 30 years there have been many studies relating two of these views histological and audiometric Some of the conclusions drawn from similarities in the results of these studies are relevant to the present study of impulse noise damage in rhesus monkeys.

Frequency localization

All investigators found that high frequency tones were detected by basal and low frequency tones by apical cochlear structures Over a considerable range a nearly linear spatial distribution on the organ of Corti was found for the logarithmic frequency scale (Schuknecht 1960)

Redundancy

Destruction of hair cells without significant loss of the nerve fiber population and cochlear supporting structures was not always related to a concomitant loss in pure tone hearing sensitivity

This principle was apparent when Neff (1947) studied the partially sectioned auditory nerve of cats For example his Cat 4 showed normal sensitivity for an 8 kHz tone while retaining no more than 20% of the nerve fibers in the region responsible for detection of this signal Similarly Elliott (1961) studying mechanically-damaged and noise-damaged cats found that for the low and middle frequency range absolute thresholds are normal when only 5 to 10% of the innervation remains so long as the area of involvement is only a few millimeters long Elliott also found the same redundancy for pitch discrimination while Elliott & McGee (1965) found it for intensity discrimination The same principle is reflected in Bredberg s (1968) cross sectional study of hair cell loss in human ears

Differences in redundancy as a function of frequency

Although this principle cannot be conclusively demonstrated by any one study it is supported by several For example Neff's Cat 8 had a fairly uniform loss of nerve fibers over most of the organ of Corti Yet it retained normal hearing sensitivity only for 500 Hz and below The magnitude of hearing loss (in dB) seems to be less after damage to the apical ganglion cells than after damage to the basal ones (as

In conducting the research described in this manuscript, the investigators adhered to the "Guide for Laboratory Animal Facilities and Care" as promulgated by the Committee on the Guide for Laboratory Animal Facilities and Care of the Institute of Laboratory Animal Resources National Academy of Sciences—National Research Council

and proceeded inward to the outer hair cells In this case the outermost third row of sensory cells would receive the greatest vibration and the vibration would diminish as it moved inward toward the modiolus This type of radial gradient of damage in acoustic trauma would also be consistent with the hypothesis that the different rows of hair cells have differential thresholds with the outer most rows having lower thresholds than the inner hair cells (cf Lynn & Sayers 1970)

The origin of the unusual osmophilic formations on the surface of Reissner s membrane remains obscure The trauma might have caused extrusion of cellular material from the epithelial cells which lined the free endolymphatic surface Possibly these represented a process of phagocytosis in the damaged cochleae

The explanation for the variability in damage to the cochlea by impulse noise or any other type of intense sound exposure is not yet clear However every human and probably every animal especially on the level of the primates differs in many infinitesimal ways from every other One might reasonably speculate that such differences extend to the inner ear Even a minute difference in the alignment of the oval window with the curvature of the lower basal turn of the cochlea would change both the impact of the shock wave of the noise impulse and the distribution of its energy to cochlear structures

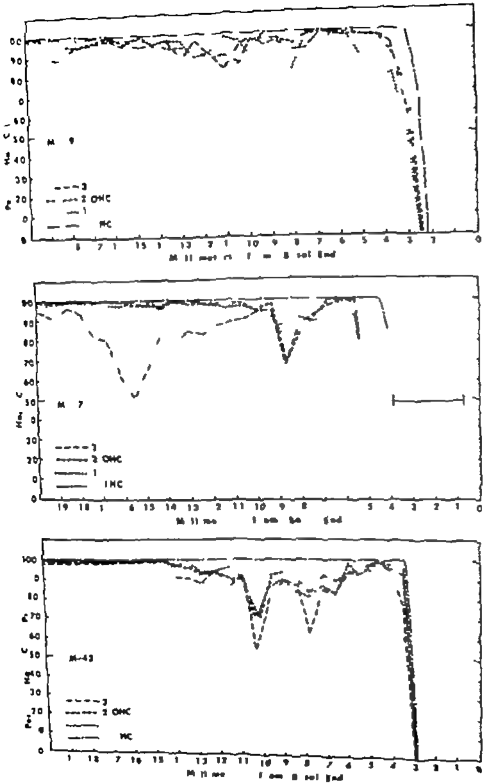

Fig. 23. Hair cell percentage graphs for the three monkeys with the least damage (M-49, M-47 and M-43).

in Elliott 1961) When histological measures were restricted to hair cells rather than ganglion cells the principle was still applicable Thus correlating post mortem hair cell loss with audiometric data of 27 human ears Bredberg (1968) found that up to 40% of the outer hair cells can be lost at 30 mm from the base without a hearing loss exceeding 15 dB at 250 Hz. Yet a 25% loss at 7 mm from the base was related to a hearing impairment of 20–30 dB at 8 kHz

Spread of fields of excitation as a function of intensity

When abrupt transitions between damaged and undamaged elements were achieved by mechanical puncture or ototoxic drugs the slope of the audiogram was shallower than would be expected from a strict frequency localization These shallow audiometric slopes might have reflected the spread in fields of excitation as the intensity of test stimuli was increased (Schuknecht 1960) For lesions in the apical half of the cochlea the ascending audiometric slope was observed to be increasingly steep as the damaged region extended farther basalward Schuknecht found that the relation of the ascending audiometric slopes to extent of damaged area ranged from 0 20 mm/dB in the apex to 0 056 mm/dB in the basal turn of the cochlea Still steeper descending audiometric slopes were recorded by Stebbins Miller Johnsson & Hawkins (1969) for basal lesions in rhesus monkeys

Regions of hypersensitivity

In many audiograms both human and animal a region of depressed hearing sensitivity has been found to be bordered by a region of increased sensitivity at some time after exposure to intense noise Most researchers in psychophysics disregard such negative threshold shifts A decrease in threshold may merely mean the animal has lowered its criterion for a response Without a measure of the animal s criterion such as found in signal detection theory (Green & Swets 1966) there is no way to evaluate a negative threshold shift However the concept of a negative threshold shift is theoretically feasible if auditory neurons are normally masking each other through lateral inhibition (cf Békesy 1967) It follows that the destruction of one set of neurons or hair cells might release a neighboring population from inhibition or masking This theoretical explanation was developed by Carterette (1969) who discussed a number of examples from published studies

The above conclusions are not exhaustive They have been presented to underscore the major features of the present study The last four principles can only degrade the correlation between auditory sensitivity and histological measures In spite of this problem most studies have reported some degree of correlation between histology and behavior This was also true for the present study in which the correlation has been expressed in two ways eta coefficient and visual comparisons

Procedure

Using the place theory of hearing sensitivity thresholds at each frequency tested were related to hair cell percentages at specific distances along the basilar membrane The specific distances representative of the test frequencies were calculated by earlier workers (Békésy & Rosenblith 1951 Schuknecht 1960 and Stebbins Miller Johnsson & Hawkins 1969) These distances along the basilar membrane were related to the test frequencies in the following manner 14 000 Hz at 4 0 mm 10 000 Hz at 6 0 mm 8 000 Hz at 8 0 mm 4 000 Hz at 11 5 mm 2 000 Hz at 15 0 mm and 1 000 Hz at 18 0 mm Since the hair cell percentages represented half millimeter segments each point of comparison actually included 0 25 mm on either side of the reference point

The highest frequency tested in the experimental animals was 14 000 Hz with its place representation at about 4 0 mm along the basilar membrane Since hearing in monkeys

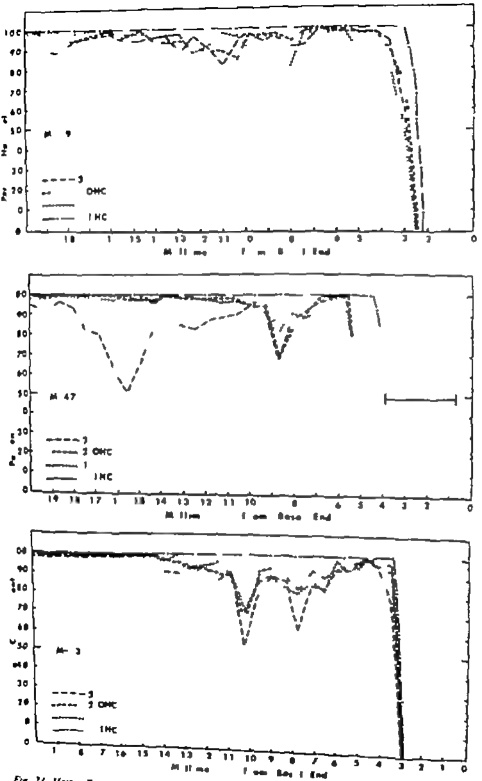

Fig. 21. Hair cell percentage graphs for the three mon-keys ath the least damage (M-49 M-47 and M-43).

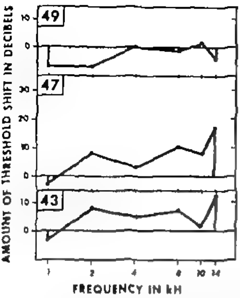

Fig 24 Profiles of hearing loss for the three monkeys *with the least histological damage (M-49 M-47 and M-43)* Negative values indicate an impro ement of postexposure threshold over pre-exposure threshold

confined to an area so narrow that it did not affect the audiogram

Monkeys 47 and 43 had both similar hair cell percentage graphs (Fig 23) and similar threshold shifts (Fig 24) In addition to the *scattered losses similar* to those in M-49 these two monkeys also showed notches in one or more rows of hair cells Presumably these and all other notches of hair cell loss reflected points of maximal stress occurring during im*pulse noise exposure M-47 suffered a notch* of hair cell loss in the third row of outer hair cells at 15 5 mm but this animal had no more hearing loss at the appropriate frequency ? kHz than M-43 The other notches (at 9 mm for M-47 and at 10 5 and 7 5 *mm* for M-43) probably account for the similar threshold

ranges up to 40 000 Hz the complete destruction *of the initial 2 0 mm to 3 0 mm* of the organ of Corti and the accompanying myelinated nerve fibers could not be related to the residual hearing in these animals

Visual comparisons

In the preceding description of the cochlear histopathology the monkeys were divided into three groups according to the variable pat terns of hair cell destruction Each group was related to its respective audiograms

Group I included the three animals (M-43 M-47 and M-49) with the least cochlear dam age *(Fig 23) and the smallest permanent* threshold shifts (Fig 24) M-49 retained nor mal hearing for all test frequencies and per formed even better at 1 and 2 kHz after noise exposure than before Perhaps this improvement reflected a release from inhibition brought about by destruction of the initial 2 5 mm of the organ of Corti Along the rest *of the basilar membrane all inner hair cells* and most outer hair cells were present (Fig 23) The largest outer hair cell loss of about 20% occurred in *the first or innermost row in* the lower basal turn This loss however was

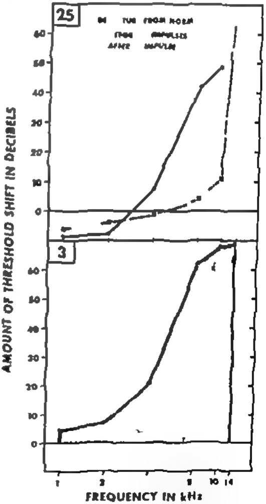

Fig 25 Profiles of hearing loss for two monkeys with *damage concentrated in the basal area of the organ of* Corti (M 25 and M 3)

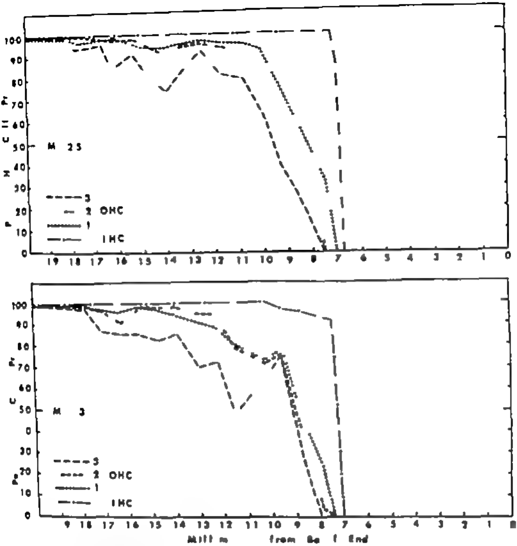

Fig. 26. Hair cell percentage graphs from tw monkeys th damage concentrated in the basal area of the organ of Corti (M 25 and M 3)

hifts at 4 and 8 kHz in these animals The main difference between the two animals hearing was at 10 and 14 kHz where the threshold shift of M-47 was about 5 dB greater than that of M-43 This difference was mirrored by the hair cell percentages M-47 had the larger lesion at the base

Group II included two monkeys whose pre-exposure audiograms were different but whose postexposure threshold shifts were quite similar (Fig. 25) M-3 was one of the nine normal monkeys. The other M 25 was screened out as abnormal because this animal s pre-exposure audiogram showed a 65 dB hearing loss at 1? kHz and no measurable sensitivity at 14 kHz. A comparison of its hearing thresholds with the median threshold values of the group of nine normal monkeys yielded the dotted line in Fig 25 The loss between 10 and 14 kHz was abrupt and reminiscent of that produced by ototoxic drugs (Stebbins Miller Johnsson & Hawkins 1969) Although no past history of ototoxic drug dosage could be established it seemed a likely hypothesis.

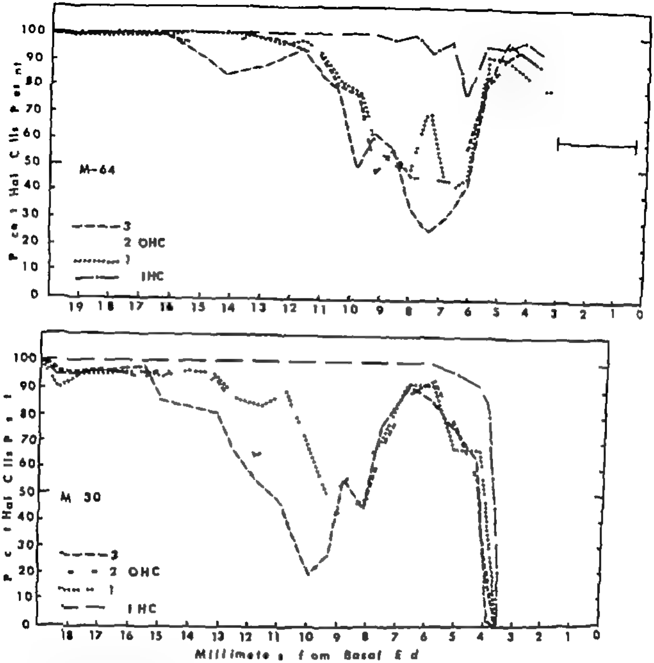

Fig 27 Hair cell percentage graphs for two monkeys with moderate notches in the region of 7 to 11 mm from the base (M-64 and M 30)

(The subject had been inherited from another laboratory.)

One exposure (two impulses) gave M 25 the hearing loss profile drawn in solid line (Fig 25) The slope of this loss profile was about the same as the loss profile for M 3 who received its loss after exposure to 10 impulses The hair cell percentage graphs were also similar (Fig 26) Each cochlea had a completely denuded area along the first 7 mm from the base Each had the same gradient of damage (least in the inner hair cells and increasingly more in each successive row of outer hair cells) Both cochlear damage and postexposure hearing loss were somewhat greater in M 3 than in M 25 The 73 dB threshold shift at 14 kHz for M 3 is to be questioned since this animal was undergoing additional loss at this frequency between the 32nd and 64th day after exposure Hair cells

and nerve fibers might have still been in the process of degeneration (cf Hamernik, Henderson & Sitler 1972)

Of the ten monkeys, these two M 25 and M 3 had results that were most similar to the rhesus monkeys described by Stebbins Miller Johnsson & Hawkins in which ototoxic drugs produced cochleae divided into two regions an apical region with virtually no hair cell loss and a basal region of complete hair cell loss. The difference between results in the two studies was in the size of the area of transition For the ototoxic losses the transition between 95% and 0% hair cells covered 1 to 2 mm. For impulse noise losses in the present study the transition covered about 8 mm Mirroring this difference was a difference in the slopes of the hearing loss profiles for the two groups of monkeys. Conceivably M 25 with its pre and postexposure hearing losses demonstrated both kinds of pathology

Group III included half the monkeys in the study (M 2 M-4 M 30 M 39 and M-64) Each had a major notch of outer hair cell loss falling between 9 and 11 mm from the base (Figs 27 29 and 31) The size of this notch varied For M 30 and M-64 its average depth was 50% (Fig 27) while for M-4 and M-39 its average depth was 85% hair cell loss (Fig 29) It was only this latter group that showed corresponding dips in the post exposure loss profiles (Fig 30)

For the monkeys with the smaller notches of hair cell loss M 30 and M-64 the principles of redundancy with greater redundancy for low frequencies and spread of excitation might have interacted to obscure the relationship between audiometric thresholds and the locus of maximal hair cell loss Thus both monkeys showed increasing loss as a function of frequency but neither showed an audiometric dip (Fig 28) M-64 with a notch of hair cell loss centered about 3 mm closer to the base than M 30's, had less threshold shift at 1 and 2 kHz and a greater shift at 14 kHz than M 30

For the two animals with the deepest notches of hair cell loss the width of the notch seemed to affect the profile of loss (Fig 30) For M-4 with a notch of hair cell loss that was narrow and centered at 9 mm, hearing loss was maximal (34 dB) at 8 kHz with much less hearing loss at adjacent frequencies (4 and 14 kHz) In contrast, M 39 had a greater hearing loss (47 dB) spread over two octaves (4 and 8 kHz) M-4 had a large notch of missing inner hair cells which might have been related to the large postexposure hyper sensitivity developed in this animal (cf theoretical formulation of Lynn & Sayers 1970) At 64 days after exposure hearing sensitivity thresholds were improved by 10 dB at 1 kHz and 12 dB at 2 kHz.

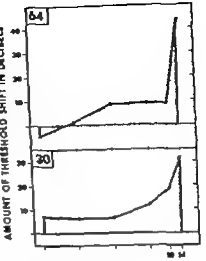

Fig 28 Profiles of hearing loss for two monkeys with moderate notches in the region of 7 to 11 mm of the base (M-64 and M-30)

The loss profile for the fifth animal, M 2, represented the transition between the less severe profiles of M 30 and M-64 and the "dip profiles of M-4 and M 39 Like M 30 and M-64 the hearing loss was greatest at the high frequencies of 10 and 14 kHz, but also included 4 and 8 kHz (Fig. 31) Unfortunately a significant area of the outer hair cells was inadvertently destroyed in the surgical preparation of the cochlea of this animal However hair cell counts were interpreted as indicating that this area had outer hair cell

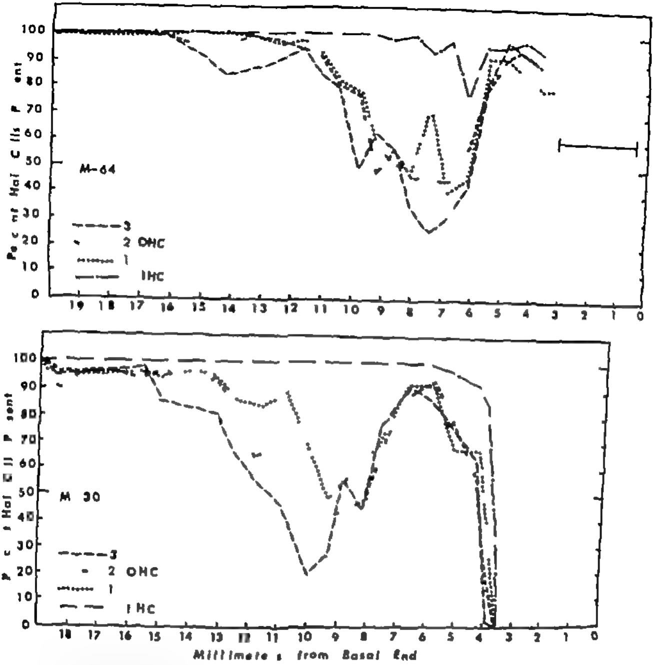

Fig 27 Hair cell percentage graph for two monkey with moderate notches in the region of 7 to 11 mm from the base (M-64 and M 30)

(The subject had been inherited from another laboratory)

One exposure (two impulses) gave M 25 the hearing loss profile drawn in solid line (Fig 25) The slope of this loss profile was about the same as the loss profile for M 3 who received its loss after exposure to 10 im pulses The hair cell percentage graphs were also similar (Fig 26) Each cochlea had a completely denuded area along the first 7 mm from the base Each had the same gradient of damage (least in the inner hair cells and increasingly more in each successive row of outer hair cells) Both cochlear damage and postexposure hearing loss were somewhat greater in M 3 than in M 25 The 73 dB threshold shift at 14 kHz for M 3 is to be questioned since this animal was undergoing additional loss at this frequency between the 32nd and 64th day after exposure. Hair cells

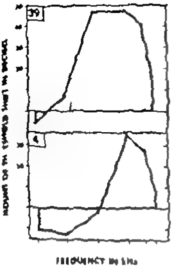

Fig. 30. Profiles of hearing loss for two monkeys with l-arged notches in the region of 7.5–11 mm of the base (M 4 and M 39).

been used over the range of 4 to 10 kHz some of the other notches of hair cell loss might have been mirrored in the profile. On the other hand the redundancy spread of excitation and release from inhibition mentioned in the Introduction might still have masked the notches of hair cell loss even in a finer-grained audiogram. Using pure tones separated by only 0.5 octave behavioral audiograms do not reflect narrow wedges of hair cell loss in the chinchilla (Eldredge 1972).

Admittedly it was difficult to predict the state of an individual animal's hair cells by studying his pure tone audiogram. Hearing losses seemed to be a function of both the percentage and the extent of the hair cell loss along the basilar membrane. However when data were pooled from all animals there was

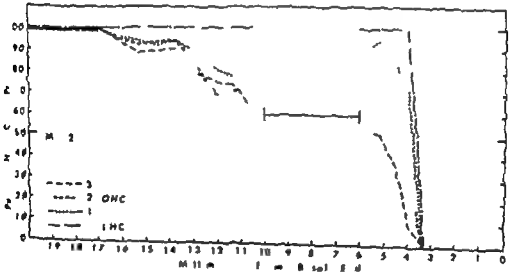

Fig. 31. Hair cell percentage graph and profile of hearing loss for M 2. This subject's audiogram represents a transition between those of M 30, M-64 and those of M-4, M-39.

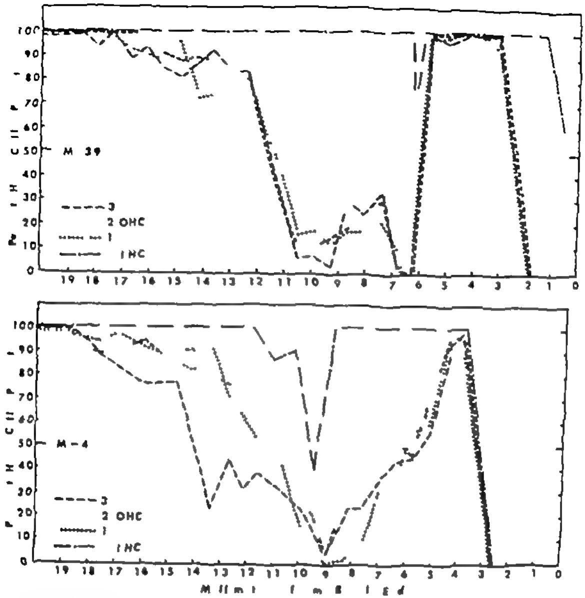

Fig 29 Hair cell percentage graphs for two monkeys with large notches in the region of 7 to 11 mm of the base (M-4 and M 39)

degeneration This was deduced from the observation that more outer hair cells were present at the basal edge of the artifact than at the apical edge Inner hair cells and myelinated nerve fibers were present in the artifact region so that the organ of Corti was not entirely destroyed by acoustic trauma The [illegible] dB SPL hearing threshold at 4 kHz probably corresponded to the average 20% outer hair cell loss between 11 0 mm and 13 5 mm

Statistical comparison

The particular noise impulses used appeared to damage the monkey cochleae in two areas (1) at the base of the cochlea and ( ) somewhere between 7 and 11 mm from the base In severely damaged monkeys (M 5 and M 3) the basal lesion was expanded into the second region For these monkeys the graphs of the hair cell percentages were easily matched to the shape of the loss profiles However in monkeys who suffered varying amounts of hair cell loss in both regions there was often a mismatch between the shapes of the hair cell graphs and the profiles For instance a small hair cell loss (50%) at 7 to 11 mm could not be matched to a dip in the hearing loss profiles If more pure tones had

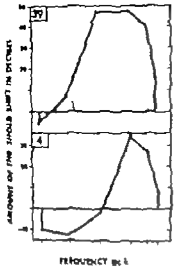

Fig. 30. Profiles of hearing loss for two monkeys with largest notches in the region of 7.5–11 mm of the base (M-4 and M-39).

been used over the range of 4 to 10 kHz, some of the other notches of hair cell loss might have been mirrored in the profile. On the other hand, the redundancy, spread of excitation, and release from inhibition mentioned in the Introduction might still have masked the notches of hair cell loss even in a finer-grained audiogram. Using pure tones separated by only 0.5 octave, behavioral audiograms do not reflect narrow wedges of hair cell loss in the chinchilla (Eldredge, 1977).

Admittedly, it was difficult to predict the state of an individual animal's hair cells by studying his pure tone audiogram. Hearing losses seemed to be a function of both the percentage and the extent of the hair cell loss along the basilar membrane. However, when data were pooled from all animals, there was

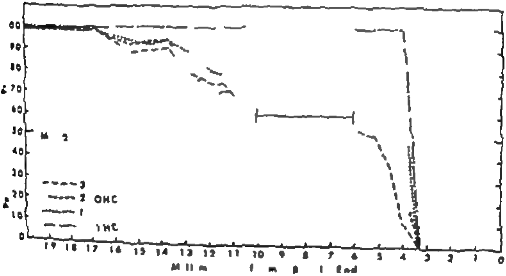

Fig. 31. Hair cell percentage graph and profile of hearing loss for M-2. This subject's audiogram represents a transition between those of M-30, M-64 and those of M-4, M-39.

a statistically significant relationship between hearing level and hair cell loss The eta coefficient (Downie & Heath 1965) was computed for the averaged outer hair cell percentages (at the places on the basilar membrane thought to be representative for each frequency) and the hearing thresholds at each frequency The resulting correlation ratio was 0 85 The F value was significant beyond the 0 01 level of probability Therefore the percentage of outer hair cells present was significantly related to the hearing threshold seen at 64 days after noise exposure The value of this correlation coefficient is nearly equal to that reported by Miller Watson & Covell (1963) ($r=0$ 83) for the cat

General Summary

Eleven rhesus monkeys surgically deafened in the right ear were tested in a shuttlebox for pure tone sensitivity at 1 2 4 8 10 and 14 kHz. The behavioral technique, avoidance conditioning was under the control of a human observer who used a descending method of limits to determine threshold. Using these methods none of the 11 appeared to have normal audiograms the tenth had a high frequency loss of unknown origin. The eleventh did not learn the avoidance task and was withdrawn from the experiment.

Following this initial audiometric testing, all 10 monkeys were exposed to two impulses of 168 dB peak SPL and tested for temporary threshold shift (TTS). In addition the nine normal monkeys were exposed to 12 min of recorded tank noise a second and a third "2-impulse exposure and a 10-impulse exposure (in that order). Two animals received a final 20-impulse exposure. TTS was evaluated after each exposure and time was allowed for recovery between exposures.

For the tank noise monkeys showed a greater TTS than a group of new recruits exposed to the same noise. After tank noise TTS recovered as a linear function of the logarithm of recovery time but after impulse noise recovery was much more variable. In some cases more threshold shift was seen at an hour after exposure than at 30 min after exposure.

The dynamics of the ears seemed to change during the course of repeated exposures. For example seven of the nine monkeys showed less TTS at 5 min after the second than at the same time after the first exposure to tank noise. The correlation between TTS_5 for these two exposures was -0.74. For impulses eight of nine monkeys showed less absolute shift at 1 kHz after the third 2-impulse exposure than after the first. However six of the nine animals showed more absolute shift at 8 and 14 kHz after the third 2-impulse exposure. At the end of all exposures eight of the original 10 showed increased sensitivity at 1 kHz.

Following the final impulse exposure recovery of threshold was studied for 64 days. Although median shift was greatest at 8 or 10 kHz during the first eight days it was greatest at 14 kHz at the end of 64 days. Only two monkeys suffered a maximum dip in their audiogram at 4 or 8 kHz. Correlations made between the amount of permanent threshold shift (PTS) seen at 64 days and the TTS seen after the first 2-impulse exposure were close to zero.

The second laboratory perfused and dissected the cochleae and made them into surface preparations. Sections were studied under the phase contrast microscope and hair cell counts were made without knowledge of the behavioral audiograms. Two areas of damage were noted, one in the cecum vestibulare at the beginning of the basilar membrane and the other at 8–10 mm from the base. For the latter transitions from normal to damaged hair cells were more abrupt on the basal than on the apical side. Damage tended to be greatest in the third row of outer hair cells and least in the inner hair cells. When the organ of Corti remained partially intact the inner hair cells usually appeared to be normal. The reticular lamina was extremely durable. In half of the cochleae a longitudinal separation between Hensen's cells and Deiters cells was observed. Darkly stained myelinated nerve fibers were missing in the hook area and lowermost turn of all ears. When seg-

ments of the organ of Corti were destroyed narrow wedges of myelinated nerve fibers were also missing. However, in one ear two wedge-shaped losses were seen opposite an apparently normal organ of Corti.

Based on the calculations of earlier workers, sensitivity thresholds at each frequency tested were related to hair cell percentages at specific distances along the basilar membrane. The correlation between the averaged outer hair cell loss of the 0.5 mm segments and threshold was 0.85. When notches occurred at 8–10 mm of the base, a hearing loss of greater than 15 dB at 2, 4, or 8 kHz was found only when damage to one of the rows of outer hair cells exceeded 80% in at least one 0.5 mm segment.

INTRODUCTION

The lateral vestibular nucleus is an important vestibular relay station. It is the sole origin of the massive vestibular pathway to the various levels of the spinal cord. It contributes strategically to the control of muscular coordination and maintenance of equilibrium. Recent fine structural studies have essentially increased our knowledge concerning its structure, but only two investigations have been reported on the pre- and postnatal development of this nucleus. It has been shown in the chick that the cells of this part of the vestibular nuclear complex are derived from the medial part of the matrix of the basal lamina, while the cells of the other vestibular nuclei originate from the dorsal part of the alar lamina (Vraa-Jensen, 1956). Only one investigation (Hauglie-Hanssen, 1968) deals with the structure of the nucleus in the newborn. Using various modifications of the Golgi method this paper showed that the cyto- and fibroarchitectures of the lateral vestibular nucleus in newborn kittens, rats and mice are quite similar to the corresponding adult structures. However, the postnatal ultrastructural development of the nucleus has not been studied systematically age group by age group. It seems reasonable to assume that a thorough understanding of the fine structure of the neurons and the distribution of nerve endings, as well as the formation of synapses at various stages of development would provide a means of better understanding the physiological differences at different developmental stages. A basis would thus be created for neurophysiological studies on the development of the vestibular function.

The postnatal growth and development of mammalian nerve cells in general is not completely understood. The same is true for the development and formation of synapses in the central nervous system, where the available data is meagre. It therefore also seemed to be of great general interest to elucidate the morphological events in the lateral vestibular nucleus from birth to adult age, paying attention in particular to the postnatal development of the nerve cells, structure of the neuropil, synaptic connections, glial cells, and their relations to neurons.

INTRODUCTION

The lateral vestibular nucleus is an important vestibular relay station. It is the sole origin of the massive vestibular pathway to the various levels of the spinal cord. It contributes strategically to the control of muscular coordination and maintenance of equilibrium. Recent fine structural studies have essentially increased our knowledge concerning its structure but only two investigations have been reported on the pre- and postnatal development of this nucleus. It has been shown in the chick that the cells of this part of the vestibular nuclear complex are derived from the medial part of the matrix of the basal lamina, while the cells of the other vestibular nuclei originate from the dorsal part of the alar lamina (Vraa-Jensen, 1956). Only one investigation (Hauglie-Hanssen, 1968) deals with the structure of the nucleus in the newborn. Using various modifications of the Golgi method this paper showed that the cyto- and fibroarchitectures of the lateral vestibular nucleus in newborn kittens, rats and mice are quite similar to the corresponding adult structures. However the postnatal ultrastructural development of the nucleus has not been studied systematically age group by age group. It seems reasonable to assume that a thorough understanding of the fine structure of the neurons and the distribution of nerve endings, as well as the formation of synapses at various stages of development would provide a means of better understanding the physiological differences at different developmental stages. A basis would thus be created for neurophysiological studies on the development of the vestibular function.

The postnatal growth and development of mammalian nerve cells in general is not completely understood. The same is true for the development and formation of synapses in the central nervous system, where the available data is meagre. It therefore has seemed to be of great general interest to elucidate the morphological events in the lateral vestibular nucleus from birth to adult age, paying attention in particular to the postnatal development of the nerve cells, structure of the neuropil, synaptic connections, glial cells, and their relations to neurons.

In the last century Deiters described a group of large nerve cells in the brain stem of man and certain other mammals. The same cellular group has been described later by numerous investigators under the name of Deiters' nucleus or nucleus vestibularis lateralis (the lateral vestibular nucleus) of Deiters. Other names used in the literature are "grosszelliger Vestibularískern" and "noyau à grandes cellules de l'acoustique". Both the terminology employed by the earlier authors and their descriptions of the vestibular nuclei contain discrepancies and cause confusion. While in 1887 von Monakow defined as the nucleus of Deiters that part of the vestibular nuclear complex in which the giant nerve cells undergo chromatolysis following lesions at the rostral level of the spinal cord, a definition according to which this nucleus comprises extensive parts of the entire vestibular nuclear complex was adopted by many other anatomists (e.g. Lewy, 1910; Fuse, 1912; Muskens, 1913–14; Winkler & Potter, 1914; Meessen & Olszewski, 1919). The term was used in the restricted sense by Sabin (1897), Ramón y Cajal (1896, 1909), and Ariëns Kappers et al. (1936). This is also in agreement with the modern definition (Brodal & Pompeiano, 1957).

According to Brodal & Pompeiano (1957) in the young cat the lateral vestibular nucleus of Deiters includes that part of the vestibular nuclear complex which is characterized by the presence of giant cells of Deiters. These giant cells are usually multipolar and show considerable variations in size and shape. They are more numerous and somewhat larger in the dorsocaudal than in the rostroventral part of the nucleus. The lateral vestibular nucleus also contains smaller cells of various sizes. There are both medium-sized, frequently oval or spindle-shaped cells and small round or oval cells. These types are more numerous in the rostral part of the nucleus. At the lateral border of the nucleus there is a small group of medium-sized cells, labelled L. Just as previously Ramón y Cajal (1909) and Fuse (1912), Brodal & Pompeiano suggested that the interstitial nucleus of the vestibular nerve of Cajal (noyau interstitiel du nerf vestibulaire) can be an aberrant part of Deiters' nucleus. The cells in this site are chiefly elongated and medium-sized, but giant cells of the type found in the lateral vestibular nucleus also occur. In addition to the above-mentioned criteria, Brodal & Pompeiano proposed certain landmarks by which the lateral vestibular nucleus may be distinguished from other parts of the vestibular nuclear complex and the neighbouring areas of the brain stem. Furthermore, they pointed out that of the whole vestibular complex, this nucleus appears in many respects to be the part most clearly characterized as a separate unit. Besides having a specific cytoarchitecture it appears to differ from the other classical vestibular nuclei

I thei exhausti e investigations of the lateral vestibular nucleus Mugnaini et al. (1967 b) used both light microscopy of semithin sections stained with toluidine blue and electron microscopy f the ultrastructure in both normal dult cats and after damage to the primary estibula fibres (Mugnaini et 1 1967 a) and the cerebello-estibula fibres (Mugnaini & W lberg, 1967) The estibular nuclei in the rat were systematically investigated for the first time by Sotelo & Palay (1968) who described the lateral estibular nucleus f the adult rat mainly on the fine structural level but also on the basis of light microscopy of semithin toluidine blue sections using the neurofibrillary methods of both Golgi-Rio Hortega and Cajal. In a second study by the same authors (1970) the synaptic structure f the lateral vestibular nucleus f the dult rat was described in great deta l and the findings were compared with the result previously reported in the cat (Mugnaini et al., 1967 b) Significant d fferences were observed between these two animal species with regard to the synaptic organization of corresponding nuclei A third study by Sotelo & Palay (1971) dealt with the altered axons and axon terminals normally occurring in the lateral est bul nucleus.

with regard to embryological derivation (Vraa-Jensen 1956). It also stands out as a particular entity more clearly than the remaining nuclei with regard to afferent and efferent fibre connections. Functionally, too, the lateral nucleus is a relatively independent part of the vestibular nuclear complex. It receives important afferent fibres from the vestibular apparatus, the cerebellum and the spinal cord. The course and central termination of the primary vestibular fibres were described by some early anatomists (Koelliker 1891, Held 1892, Ramón y Cajal 1909, Leidler 1914) and later by Lorente de Nó (1933) and Walberg et al. (1958). More recently, Stein & Carpenter (1967), Mugnaini et al. (1967 a) and Gacek (1969) have supplied significant detailed information on the origin, course and termination of the primary vestibular fibres. Although it had long been known that the cerebellar cortex and nuclei send afferent fibres to the vestibular nuclei (e.g. Allen 1924, Hohman 1929, Rasmussen 1933, Dow 1936, 1938, Jansen & Brodal 1940, Jansen & Jansen 1955, Thomas et al. 1956), Walberg & Jansen (1961), Walberg et al. (1962) and Mugnaini & Walberg (1967) gave a minute description of the cerebellovestibular fibres and showed that the lateral vestibular nucleus is the main terminal area of these fibre connections. The third well known afferent fibre connection to the lateral vestibular nucleus consists of the spinovestibular fibres mainly originating from the lumbar cord. It was first described by Thiele & Horsley (1901), later by Hashimoto (1928) and Johnson (1954) and in greater detail by Pompeiano & Brodal (1957).

The lateral vestibular nucleus sends efferent fibres to the vestibular apparatus, to various levels of the spinal cord, and to the oculomotor nuclear complex, possibly by passage to the cortical vestibular centres. The lateral vestibular nucleus is the only one of the four classical vestibular nuclei which probably sends efferent fibres within the vestibular nerve to the vestibular neuroepithelium of the labyrinth (Gacek, 1965). On the basis of earlier studies by Rasmussen (1946, 1953) and Wersäll et al. (1951) this efferent fibre system was described by Petroff (1955) and in more detail by Rasmussen & Gacek (1958) and Gacek (1965). Supplementary investigations were published by Dohlman et al. (1958), Carpenter et al. (1959), Rossi & Cortesina (1962), Hilding & Wersäll (1962) and Iurato et al. (1971). The main efferent pathway of the lateral vestibular nucleus is the vestibulospinal tract derived exclusively from this nucleus and extending to the lumbar cord. This efferent fibre connection has been known for a long time (Monakow 1883, Lewandowsky 1904, van Gehuchten, 1904). Later it has been studied by numerous authors (e.g. Foerster & Gagel 1932, Buchanan 1937, Cooper & Sherrington, 1940). More recently Pompeiano & Brodal (1957) and Nyberg-Hansen & Mascitti (1964) have described the origin, course and termination of the vestibulospinal tract in greater detail. The third efferent pathway of the lateral vestibular nucleus, i.e. the fibres to the higher levels of the brain, has been described by Muskens (1913–14), Buchanan (1937), Szentágothai (1950, 1964) and recently in detail by Gacek (1971). The ascending tract of Deiters to the oculomotor nuclei has been thoroughly investigated but knowledge of the other termination areas is fragmentary. The remaining afferent and efferent fibre connections of the lateral vestibular nucleus of Deiters have scarcely been described. The intrinsic fibre connections within the entire vestibular nuclear complex are still obscure.

Although the fibre connections of the vestibular nuclei have been extensively studied in recent years, only a few reports deal with their fine morphological structure

In their exhaustive investigations of the lateral vestibular nucleus Mugnaini et al (1967 b) used both light microscopy of semithin sections stained with toluidine blue and electron microscopy of the ultrastructure in both normal adult cats and after damage to the primary vestibular fibres (Mugnaini et al., 1967 a) and the cerebello-vestibular fibres (Mugnaini & Walberg 1967). The vestibular nuclei in the rat were systematically investigated for the first time by Sotelo & Palay (1968) who described the lateral vestibular nucleus of the adult rat mainly on the fine structural level, but also on the basis of light microscopy of semithin toluidine blue sections using the neurofibrillary methods of both Golgi Rio Hortega and Cajal. In a second study by the same authors (1970) the synaptic structure of the lateral vestibular nucleus of the adult rat was described in great detail and the findings were compared with the results previously reported in the cat (Mugnaini et al 1967 b). Significant differences were observed between these two animal species with regard to the synaptic organization of corresponding nuclei. A third study by Sotelo & Palay (1971) dealt with the altered axons and axon terminals normally occurring in the lateral vestibular nucleus.

with regard to embryological derivation (Aras Jensen 1956) It also stands out as a particular entity more clearly than the remaining nuclei with regard to afferent and efferent fibre connections Functionally too, the lateral nucleus is a relatively independent part of the vestibular nuclear complex It receives important afferent fibres from the vestibular apparatus, the cerebellum and the spinal cord The course and central termination of the primary vestibular fibres were described by some early anatomists (Koelliker 1891 Held 1892 Ramón y Cajal, 1909 Leidler 1914) and later by Lorente de Nó (1933) and Walberg et al (1958) More recently Stein & Carpenter (1967) Mugnaini et al. Although the fibre connections of the vestibular nuclei have been extensively studied in recent years only a few reports deal with their fine morphological structure

microscope to check the position of the lateral vestibular nucleus. This area was further trimmed, and when the nucleus was found, serial sections 1 μ in thickness were made in all three directions (transverse, sagittal and frontal) for light microscopy and thin adjacent sections for electron microscopy were cut on an LKB or Reichert ultrotome with glass knife. Afterstaining was performed on grids with lead citrate (Reynolds, 1963), uranyl acetate (Watson, 1958) or both. The specimens were examined and photographed with an AEI EM 801 or Philips EM 300 electron microscope.

Light micrographs magnified 400 × were chiefly used in this study. In addition, light micrographs of lower magnification (120 × and 250 ×) were used. In order to obtain a better view of the various levels of dissection of the nucleus, the micrographs were taped together to montages. Glial cells per unit of surface area were counted on these montages.

Neurons and glial cells were measured on electron micrographs magnified about 8 000 and 20 000 × (negative 4 000 and 10 000) which were taped together to montages. Each montage mostly showed the soma of one neuron and the immediately surrounding tissue. In the various age groups about 10 each of giant, medium-sized and small neurons and glial cells of various types were measured. The results given express the variation in maximum and minimum diameter of the cell body and nucleus in 10 cells of each type, without processes. In all cells measured, the transverse section was made through the nucleolar plane.

The presynaptic axon terminals of the neurons of various sizes were classified by size and shape including their junctional zones, as suggested by Sotelo & Palay (1970), and the terms axon terminal and synapse are used in accordance with the definition given by Peters & Palay (1966). The number of various axon terminals per neuron was calculated for the different categories of neurons in the same material as the neurons and nuclei were measured. The results express the variation in number of various presynaptic terminals per cross-section of cell. Furthermore the number of synapsing axon terminals per length unit of perikaryal or dendritic surface area was calculated in the same material.

MATERIAL AND METHODS

A total of 274 Sprague-Dawley albino rats of both sexes were used in this investigation. The age distribution was as follows: 8 newborn, 6 four-day-old, 7 seven-day-old, 8 ten-day-old, 5 twenty-day-old, 6 thirty-day-old and 231 adult rats. Of the adult rats 54 were used in the electron microscopic studies. The remainder were used in various light microscopic investigations, serving as a thorough introduction into the structure of the entire vestibular nuclear complex. The newborn rats, though a few hours old, were always fixed on the day they were born. Animals over three months old were considered adult.

All rats were perfused under ether anaesthesia via the left ventricle of the heart. Simultaneously, the two jugular veins were opened and the abdominal aorta was closed by forceps to make perfusion fixation more effective. The perfusion fixation procedure was the same as has previously been described in detail by Reehardt (1969). The fixation fluid consisted of 3.5 per cent formaldehyde pro analysi grade (E. Merck AG, Darmstadt) buffered with 0.075 M phosphate to pH 7.4. The perfusion time was 15 minutes.

The brain stem with the cerebellum was dissected out in one block and then immediately placed under the stereomicroscope. The cerebellum was removed by dissection of the cerebellar peduncles with scissors as proximally as possible in order to avoid damage to the vestibular nuclei. The various parts of the fourth ventricle of the brain with their anatomical details were identified on inspection of the dorsal aspect of the preparation (Wünscher et al. 1965). The brain stem was transversely cut with a razor blade at the level of the aqueduct of Sylvius. The genu and fibres of the facial nerve could then be identified, because the plane of dissection ran through the caudal part of the superior vestibular nucleus and the rostroventral part of the lateral vestibular nucleus. A couple of slices of the vestibular nuclear region about 1 mm thick were cut with the razor blade transversely in the caudal direction and freed from tissues not belonging to the vestibular nuclei and their immediate surroundings. These specimens, which consisted of the lateral vestibular nucleus and immediately adjacent tissues, were immersed overnight in the above-mentioned fixative. The surrounding tissues served as landmarks for the identification of the various parts of the lateral vestibular nucleus.

The tissue pieces were then washed for two hours in several changes of ice-cold 0.075 M phosphate buffered to pH 7.4 and refixed for two hours in 2 per cent OsO_4. Dehydration was carried out in a graded ethanol series, after which the specimen were embedded in Epon (Luft 1961) or in Epon Araldite (Fr[illegible]nk & Fr[illegible] 19[illegible]1). Sections 1 μ thick were stained with toluidine blue and examined under the light

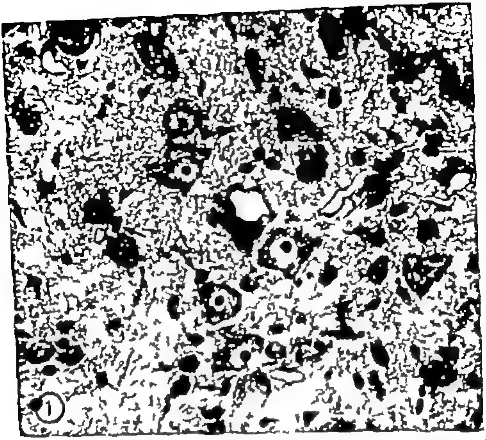

Fig. 1. — Light microscopic view of the dorsocaudal part of the lateral vestibular nucleus of newborn rat. Giant neurons in groups predominate. Note the satellite position of light glial cells, marked by big arrows, and the position and grouping tendency of dark glial cells, marked by small arrows. Toluidine blue stained Epon-Araldite section. ×400.

Such communications could be seen in a number of 7–8 per cross-section of medium-sized cell. Nuclear indentations were common in neurons of all sizes.

The Nissl substance was coarse, scattered and randomly arranged. It was usually dispersed all over the cytoplasm, although in some cells the largest and heaviest stained clumps were peripherally located. This applied to neurons of all sizes, but in particular to the giant ones, which contained Nissl substance in considerably greater amounts than the medium-sized and small neurons. It should be emphasized that the location of the Nissl substance peripherally in the cytoplasm seemed to be due to chance. The cytoplasm of the giant neurons, in particular, invariably contained light vacuoles around the nucleus varying in shape.

The giant cells did not vary very much in shape. They were usually either spheroid or polygonal, but also multipolar forms occurred. The large nucleus was often peripherally situated. The cytoplasm of the giant neurons was extensive, but that of the medium-sized and small neurons was generally scanty, in the medium-sized neurons sometimes widening to a perikaryon containing an abundance of cell organelles.

RESULTS

Newborn rats

GENERAL FEATURES

Neurons of various sizes were evenly distributed throughout the lateral vestibular nucleus, though giant cells predominated in its dorsocaudal part (Fig. 1) The neurons mainly occurred in groups of 2–5 The neuropil was wide pale and homogeneous in appearance Glial cells were present in slightly lesser number than neurons. The glial cells could be divided into two distinct types. There was a smaller variety "dark glial cells" with nuclei heavily staining with toluidine blue Often occurring in groups of 3–5 they were uniformly distributed over the neuropil. This type which predominated, was seldom encountered close to neurons "Light glial cells" on the other hand were often found in the immediate vicinity of neurons. These cells had larger and lightly staining nuclei. Besides glial cells, nerve fibres of various sizes and small capillaries were distinguished with the light microscope in the weakly staining neuropil.

Ultrastructurally unmyelinated nerve fibres, often identified as axons, coursed in various directions. The majority of these nerve fibres were thin and disposed in bundles of various sizes. The thinnest fibres had a diameter of 0 1–0 4 μ Considerably thicker nerve fibres were also relatively numerous. The thickest measured 1 0–1.5 μ in diameter These were still more often identified as axons. They also differed from the thinner nerve fibres by frequently establishing synapses with one another and also with the dendrites in contact with them. The small nerve fibres seemed to be the site of synapses considerably less often. Glial cells with a scanty cytoplasm and clumsy extensive processes surrounded the main bulk of neurons.

NEURONS

Their nuclei were large, occupying over half of the surface area even in giant neurons, and spherical or elongated in shape Because of the considerably heavier peripheral staining of the nucleoplasm the boundary to the cytoplasm was occasionally indistinct, though mostly readily distinguished. At the centre of the nucleus a large well defined nucleolus was clearly seen against the pale background.

The chromatin was in general uniformly distributed throughout the nucleoplasm In the medium-sized and small neurons the two layers of the nuclear membranes were often more widely separated than usual and formed perinuclear cisterns, frequently communicating with the tubules of the rough endoplasmic reticulum.

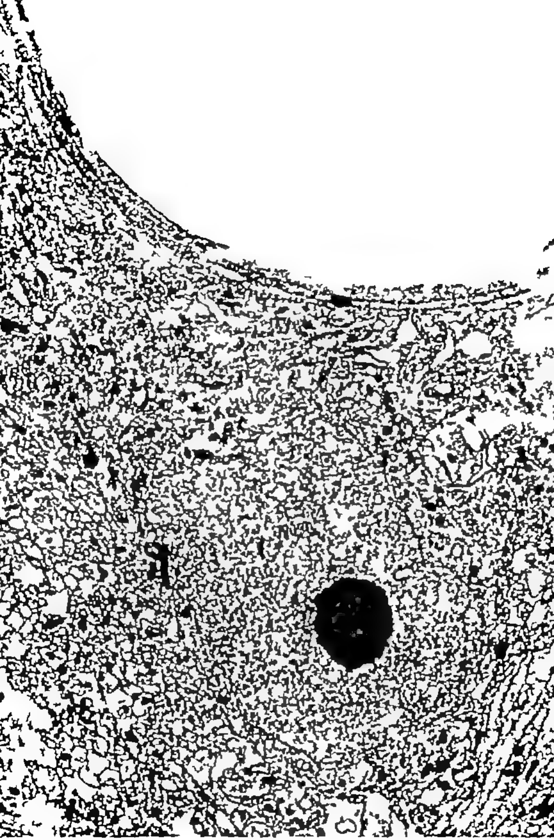
Glial cells with a scanty cytoplasm and clumsy extensive processes surrounded the main bulk of neurons.

NEURONS

Their nuclei were large occupying over half of the surface area even in giant neurons, and spherical or elongated in shape Because of the considerably heavier peripheral staining of the nucleoplasm the boundary to the cytoplasm was occasionally indistinct, though mostly readily distinguished At the centre of the nucleus a large, well defined nucleolus was clearly seen against the pale background.

The chromatin was in general uniformly distributed throughout the nucleoplasm In the medium-sized and small neurons the two layers of the nuclear membranes were often more widely separated than usual and formed perinuclear cisterns, frequently communicating with the tubules of the rough endoplasmic reticulum



The giant cells varied in diameter from 20–50 μ their nuclear diameter from 15–20 μ The corresponding variations in the small neurons were from 5–15 μ and from 5–10 μ Cells measuring from 10–20 μ in longitudinal and transverse sections, with nuclei varying from 10–15 μ in diameter were considered medium sized

Cytoplasmic organelles such as the rough endoplasmic reticulum were sparse and scattered throughout the cytoplasm in the small and medium-sized neurons in the giant cells they were relatively abundant In all neurons the tubules were thick, short and often displayed swellings. In general they were disposed randomly and not in anything like parallel array The ribosomes were numerous and mostly arranged in rosettes. Their distribution in the cytoplasm was relatively uniform, although they occurred in greater number in close vicinity to the endoplasmic reticulum. Large clusters, obviously consisting of individual ribosomes, were occasionally seen in the cytoplasm of all neurons. There were numerous well developed Golgi complexes with flat or bulging cisterns in the giant and medium sized cells (Fig 2) The relatively few mitochondria were large, varying in length from 0.2–2.5 μ The few neurofilaments seemed to be located at random among other organelles, most frequently at the base of dendrites. In cross-sections of the giant and medium-sized neurons the neurofilaments sometimes seemed to run roughly parallel with one another in bundles, occasionally containing even a great number of filaments. Microtubules were infrequent, although a relatively constant finding in the peripheral cytoplasm of the larger neurons. In this age group subsurface cisterns were seen only occasionally in the giant cells. By contrast the thorns characteristic of the giant and medium sized cells of Deiters were fairly numerous They were small spines exclusively containing ribosomes scattered over the cytoplasm and never disposed in clusters. The thorns were frequently covered by axon terminals of various sizes, which synapsed on them Stacks of cisterns of endoplasmic reticulum were also observed in the cytoplasm of the medium sized neurons (Fig 3)

SYNAPSES

Axo-somatic synapses

The cytomembranes of both the giant and medium-sized neurons were almost completely covered by nerve endings of various sizes. Nerve fibres by passage dendrites and perikarya or processes of glial cells and sometimes capillaries were in immediate contact with the neuronal cytomembranes. Both large and small axon terminals were seen in great number but no clearly slender terminals. Small nerve endings predominated on the neurons of all sizes It was noteworthy however that although axon terminals of various sizes occurred in a number of 30–50 per giant cell profile only a small proportion of them synapsed on the neuron. The number of terminals

attachement plaques were less frequent on the large terminals which synapsed in the plane of section, and they also occasionally occurred in large endings which seemed to lack a synaptic junction.

Slender axon terminals making synapses on the cell bodies were not seen on the cell perikarya at this age.

The small axon terminals varied in both length and diameter from 0.2–1.0 μ. The length of their active zone was about the same as the length of the ending, and the shape was somewhat convex toward the cytomembrane. These terminals contained exclusively an abundance of agranular synaptic vesicles. No other presynaptic organelles were observed.

Axo-dendritic synapses

The number of synaptic contacts between the proximal parts of the dendrites and the surrounding axon terminals of various sizes was great (Fig. 4). On the distal parts of the dendrites similar contacts occurred in lesser number although they were more numerous than on the cell bodies. The synaptic population on the proximal parts of the dendrites per unit length of the cytomembrane was 3 to 4-fold that seen on the giant cells. Calculated on the total available material the same number and types of

synapsing on a giant cell figure varied from 4–7. The majority of these terminals were large (Table 1).

The number of synapsing terminals per medium sized neuron figure varied from 2–4. Large nerve endings were most frequent.

The small neurons were exclusively covered by small axon terminals. Of these only a very small proportion synapsed on the cell figure in the plane of section. No synapses were established on the majority of the small neurons.

The large axon terminals measured 1–2.5 μ in length and 0.5–1.0 μ in diameter. Agranular synaptic vesicles occurred in the neighbourhood of the synaptic zones, though relatively sparsely. They were spherical and varied in size from 300–700 Å. Granular (= large dense core) vesicles measuring 900–1 500 Å were seen in about half of the large terminals per section, varying in number from 1–3. The majority of the large terminals contained one small mitochondrion. Both neurofilaments and microtubules occurred in relative abundance. The large axon terminals usually each contained one "active" junctional zone, sometimes two. Desmosomal junctions or

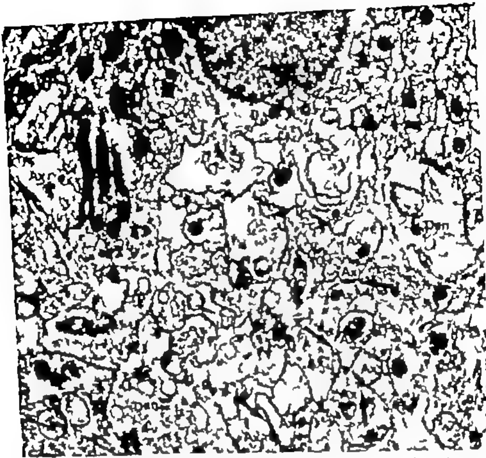

Fig 5 — Electron micrograph of the neurop l in the lateral estibula nucleus f new born rat Numerous axo-axonal contacts are formed (arrow) Abov part of light glial cell s seen × 16000

NEUROGLIA

D rk glial cells constituted 60—70 per cent of the glial cell population. Their ovoid or elongated nuclei stained heavily with toluidine blue. Sometimes their cytoplasm also ppeared either partly or entirely dark stained.

The size of this smaller type of glial cells (Fig. 2) varied from 5—7 μ. Both the nucleus and the cytoplasm stained more heavily than in the light cells. The cell organelles — small mitochondria, sometimes nicely arrayed rough endoplasmic reti culum tubules and Golgi apparatuses — were distinctly seen in the scanty cytoplasm. I dd tion to clusters of ribosomes, the cytoplasm contained uniformly distributed granular material, which ga these cells their typical dark appearance. In general, these cells were more distantly located in the neuropil, and they were only occasionally seen close to neurons (Fig. 2)

The cytoplasm of the light glial cells did not stain with toluidine blue. Compared with the dark glial cells, their nuclei stained much more lightly and were definitely larger The nucleus seemed pear-shaped or polygonal and alway gave a general impression of clumsiness I the light microscope the majority of these cells were satellites of neurons, and the cells which were not apposed to neurons were located

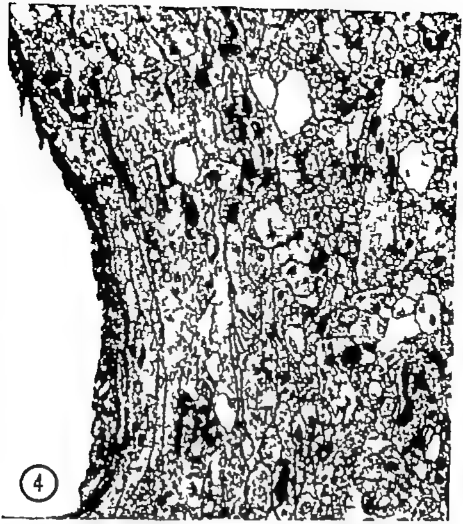

Fig. 4. — Electron microscopic view of the neuropil in the lateral vestibular nucleus of a newborn rat. To the left, the proximal part of a dendrite of a medium sized neuron is seen in longitudinal section. Axon terminals of various sizes (thick arrows) synapse on the right margin of the dendrite. × 8000

synapsing axon terminals were seen on the dendrites originating from all neurons. Terminals of both of the two slender types also occurred. The axon terminals were morphologically similar to the axo-somatic terminals, but all types of nerve endings, the small ones in particular, synapsed more frequently on the dendrites than on the cell body. Synapses were often established on the regularly occurring dendritic thorns. There were sometimes 3—4 synaptic contacts per one dendritic thorn.

Axo-axonal synapses

Axo-axonal synapses were most numerous more distantly in the neuropil (Fig. 5) where they were a constant finding. The synaptic contact was always between two adjacent relatively large axons. The extent of the synaptic zone varied from 0.3—0.8 μ; its length was determined by the size of the synapsing axon terminal. Axon terminals of various sizes or axons by passage occasionally synapsed on large axon terminals, which in turn were in synaptic contact with neuronal perikarya or dendrites. Moreover, small terminals synapsed on the axon hillock of giant neurons.

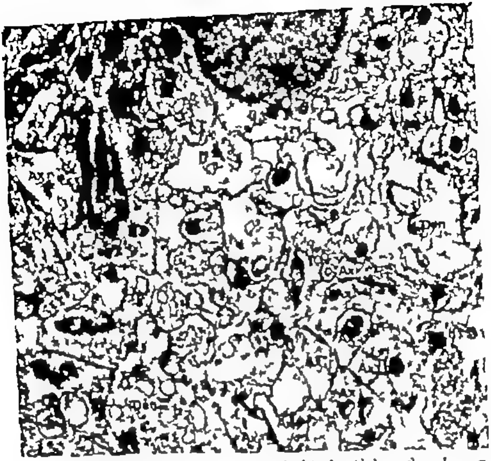

Fig. 1. — Electron micrograph of the neuropil in the lateral vestibular nucleus of newborn rat. Numerous axo-axonal contacts are formed (arrow). Above part of a light glial cell is seen. × 16000

NEUROGLIA

Dark glial cells constituted 60—70 per cent of the glial cell population. Their ovoid or elongated nuclei stained heavily with toluidine blue. Sometimes their cytoplasm also appeared either partly or entirely dark stained.

The size of this smaller type of glial cells (Fig. 2) varied from 5—7 µ. Both the nucleus and the cytoplasm stained more heavily than in the light cells. The cell organelles — small mitochondria, sometimes nicely arrayed rough endoplasmic reticulum tubules and Golgi apparatuses — were distinctly seen in the scanty cytoplasm. In addition to clusters of ribosomes, the cytoplasm contained uniformly distributed granular material, which gave these cells their typical dark appearance. In general, these cells were more distantly located in the neuropil, and they were only occasionally seen close to neurons (Fig. 2).

The cytoplasm of the light glial cells did not stain with toluidine blue. Compared with the dark glial cells, their nuclei stained much more lightly and were definitely larger. The nucleus seemed pear-shaped or polygonal and always gave a general impression of clumsiness. In the light microscope the majority of these cells were satellites of neurons, and the cells which were not apposed to neurons were located

near groups of neurons. In contrast to the dark glial cells, these light cells were only occasionally seen more distantly in the neuropil.

The glial cell figures of this larger type varied in size from 6–10 μ. Both the relatively large lobulated nuclei and the cytoplasm of these cells stained more weakly and the details of the organelles were less distinct than in the smaller type of glial cells. The cytoplasm contained a varying number of electron dense granules, which occasionally formed groups of considerable size. The structures best distinguished in the cytoplasm were fairly large mitochondria, smooth in appearance, short rough endoplasmic reticulum tubules and vesicles of various sizes. The cytoplasm frequently sent out variously shaped processes into the surrounding neuropil and the contour of the cytoplasm was sometimes indistinct. The light glial cells were satellites of neurons also as seen in the electron microscope. This relation was often so marked that either their body or a broad process was immediately apposed to the neuronal cell body. Mostly, however, they were separated from the neuron by axon terminals (Fig. 5).

Four Day Old Rats

GENERAL FEATURES

The abundance and variation of the total cell population attracted attention. The neuropil was heterogeneous and displayed topographical variations (Fig. 6). Giant and medium sized neurons were most numerous in the dorsocaudal part of the nucleus; in the rostroventral part they occurred in considerably lesser number. The disposition of the neurons into groups of 3–5 was also more distinctive in the dorsocaudal part. The details in the neuropil were more easily distinguished than before. The most striking observation, however, was the appearance of a new type of cell. These "new cells" (Figs. 6, 13 a and b), not identifiable in the light microscope as either neurons or glial cells, occurred in abundance in the neuropil. They were spheroid or elongated and had a very large nucleus, surrounded by a narrow rim of heavily stained cytoplasm. The size was about the same as that of the glial cells and small neurons. The size of these cells varied greatly and they were most numerous in the dorsal part of the nucleus. Moreover, uniformly distributed glial cells of dark and light types occurred in abundance.

Bundles of nerve fibres and dendrites originating from neurons were clearly distinguished. Capillaries of small calibre were numerous. Early myelination figures in the ventral part of the nucleus were another noteworthy feature. The fibres arriving with the vestibular nerve seemed to be most strongly myelinated. Myelinated fibres were occasionally encountered in the central part of the nucleus, but the dorsal part was free of them. In the electron microscope most of the nerve fibres of various calibres could be identified as unmyelinated axons coursing in various directions. Axons with a very thin myelin sheath could be seen especially in the fibres of large calibre (1–2.5 μ). Axo-axonal synapses consisting of small axons synapsing on one another or on larger axons were common. A considerable proportion of the neuropil was taken up by various glial cells, which generally sent off large and clumsy processes.

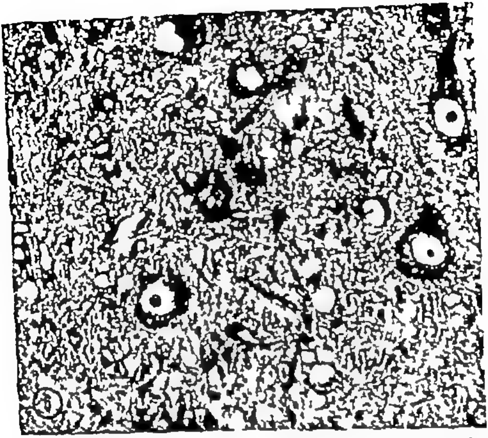

Fig. 6 – Light micrograph of the rostral part of the lateral vestibular nucleus of 4-d y old rat. Nissl substance is unevenly distributed in the cytoplasm of giant neurons, large lumps of Nissl substance and pale vacuoles are seen. In the cytoplasm of medium-sized and small neurons the Nissl substance is scanty. Note the great number of new glial cells (double small arrows) in the neuropil. Some myelinated fibres are also seen. Toluidine blue stained Epon-Araldite section. × 400

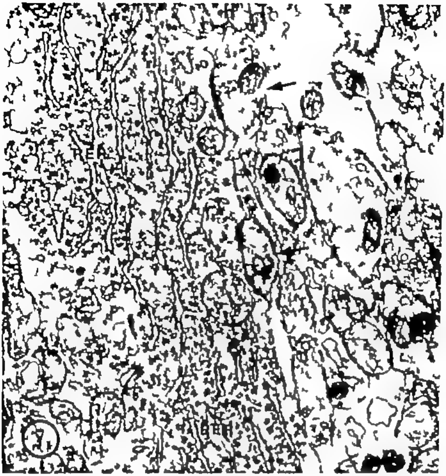
NEURONS

The nuclei of all types of neuron showed no changes in size or shape compared to the previous stage but the giant and medium-sized neurons had lost their perinuclear cisterns and the cleft between the nuclear membranes was thus throughout narrow (250–500 Å). Perinuclear cisterns with many connections to the rough endoplasmic reticulum were common in the small neurons. The Nissl substance stained heavily with toluidine blue. This was true in particular for the giant cells.

In some giant neurons the Nissl substance was relatively uniformly dispersed throughout the cytoplasm, while in others large clumps of Nissl substance were peripherally located. The staining of the cytoplasm in the medium-sized and small neurons was weak and even Nissl bodies were not clearly distinguished.

In general it was obvious that the giant cells (25–35 μ) were more pleomorphic than in the newborn rat. Multipolar and spindle-shaped forms occurred in greater number than before although spheroid and elongated cells were still most common. This may in part be due to the fact that the broad proximal parts of dendrites were



F g — Electron micrograpl of the lateral vestibular nucleus of a 1-day-old rat Highly organized rough endoplasmic reticulum and ribosomes are seen in the cytoplasm of giant neuron. Two small axon terminals (arrows) synapse on the cell body of the giant neuron × 20000

more conspicuous. The medium sized neurons (15—25 μ) were invariably spheroid or ovoid and showed uniformly distributed cytoplasm. By contrast, the cytoplasm of the small neurons (5—15 μ) was still scanty

As a rule, the amount of rough endoplasmic reticulum and the number of ribosomes increased markedly with increasing size of the neurons However there were considerable differences in the amount and shape of the rough endoplasmic reticulum tubules present in neurons of different sizes. In some giant neurons the rough endoplasmic reticulum showed beginning organization as a separate region with parallel tubules and clustered ribosomes (Fig 7) These regions were relatively extensive often scattered and not always clearly demarcated and mostly located peripherally in the cytoplasm of the giant neurons. Mitochondria neurofilaments, microtubules and numerous Golgi apparatuses were for the most part located in the cytoplasm round the nuclear membrane In other giant neurons the distribution of the cell organelles was very variable Sometimes the cytoplasm contained a small area with a rather primitive arrangement of the rough endoplasmic reticulum In the small neurons the rough endoplasmic reticulum was scanty the tubules were short and wide with numerous swellings and the ribosomes were mainly scattered all over the cytoplasm. The morphology of the medium-sized neurons (Fig 8) resembled that

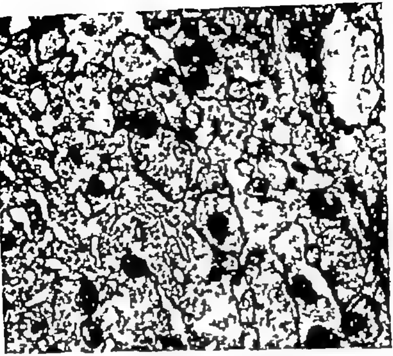


Fig. 8 — Electron micrograph showing the cytoplasm [of a] medium-sized neuron and the surrounding neuropil in the lateral vestibular nucleus [of a] 4-day-old rat. Note short and plump rough endoplasmic reticulum tubules which are not [as] full[y] organized, although the surrounding ribosomes [a]re clearly arranged in clusters. Typical small axon terminal (thick arrow) synapses on the neuronal surface. [In] the neuropil, a small [ax]on terminal probably synapses on another [ax]on (thin [ar]row). × 20000.

[O]f both the giant and the small neurons, especially the latter, however. The rough endoplasmic reticulum tubules were mainly short and wide, although narrower and longer tubules [al]so occurred. I[n] general, the rough endoplasmic reticulum and the ribosomes were distributed throughout the cytoplasm. In many cells, however, the endoplasmic reticulum was organized [a]t places into parallel arrays [o]f tubules, slightly primitiv[e] in appearance. Ribosomes occurred mostly in clusters. Neurofilaments were present in all neurons, most numerously in the giant cells. Microtubules were occasionally observed peripherally in the cell. These structures were never [a]bundant, however.

SYNAPSES

Axo-somatic synapses

The number of synaptic [ax]on terminals, on the giant neuron, had increased to 10–25, being mostly, however, unde[r] 15. The majority were small endings (*Table I*). The large ones constituted [a]bout one-third of the total number of synaptic axon terminals on the cell per section. Most synapses to the medium-sized neurons were small, even though large terminals sometimes predominated in some neurons. Usually 5–12 synapses per section were present in the medium-sized neuron.

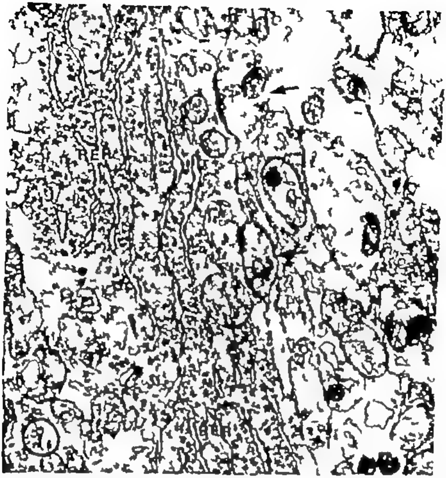

Fig — Electron micrograph of the lateral vestibular nucleus of a 4-day-old rat. Highly organized rough endoplasmic reticulum and ribosomes are seen in the cytoplasm of a giant neuron. Two small axon terminals (arrows) synapse on the cell body of the giant neuron. × [illegible]0000

more conspicuous. The medium sized neurons (15–25 μ) were invariably spheroid or ovoid and showed uniformly distributed cytoplasm. By contrast, the cytoplasm of the small neurons (5–15 μ) was still scanty.

As a rule the amount of rough endoplasmic reticulum and the number of ribosomes increased markedly with increasing size of the neurons. However there were considerable differences in the amount and shape of the rough endoplasmic reticulum tubules present in neurons of different sizes. In some giant neurons the rough endoplasmic reticulum showed beginning organization as a separate region with parallel tubules and clustered ribosomes (Fig. 7). These regions were relatively extensive, often scattered and not always clearly demarcated, and mostly located peripherally in the cytoplasm of the giant neurons. Mitochondria, neurofilaments, microtubules and numerous Golgi apparatuses were for the most part located in the cytoplasm round the nuclear membrane. In other giant neurons the distribution of the cell organelles was very variable. Sometimes the cytoplasm contained a small area with a rather primitive arrangement of the rough endoplasmic reticulum. In the small neurons the rough endoplasmic reticulum was scanty, the tubules were short and wide with numerous swellings and the ribosomes were mainly scattered all over the cytoplasm. The morphology of the medium sized neurons (Fig. 8) resembled that

Fig. 9 – Electron micrograph showing the xon of giant neuron in the lateral estibular nucleus of 4-day-old rat The well developed endoplasmic reticulum of the giant neuron does not extend into the xon hillock Numerous axon terminals of arious sizes synapse on both the xon hillock (AH) and the cytomembrane of the initial segment (IS) T light glial cells re seen At th age their processes are few in number × 8 000

All synapses on the small neurons were small. The number varied from 0–5 per cell figure.

In longitudinal sections the large axon terminals measured 2.5–4.0 μ in length and 0.5–1.2 μ in diameter. Their size had doubled. Most synaptic vesicles were agranular but 1–2 vesicles occurred in almost half of the terminals. The majority of the large axon terminals contained 1–5 mitochondria. There were usually 1–3 junctional zones per terminal. Their maximum length was 0.5 μ. Desmosomal junctions, measuring 0.4–0.6 μ in length, were also seen in most large endings.

Slender axon terminals did not synapse on the cell bodies in this age group either. The diameter of the small axon terminals was less than 1.5 μ, usually varying between 0.5 and 1.0 μ. The active zone of the small axon terminals was relatively straight, though mostly somewhat bulging with the convexity towards the cytomembrane. The small axon terminals contained numerous agranular synaptic vesicles, but 1–4 granular vesicles were also seen per section in nearly all terminals. A few mitochondria could be seen in all the synapse types. Mitochondria were rare in small terminals.

Axo-dendritic synapses

The axon terminals synapsing on dendrites were identical with the axonal endings synapsing on neuronal cell bodies with regard to shape, structure and size. Synaptic slender terminals of both types were also regularly seen. The type of axon terminal synapsing on a dendrite bore no relationship to the size of the neuron from which the dendrite originated: both large and slender terminals also synapsed on the dendrites originating from small neurons. However, most numerous were the synaptic axon terminals on the proximal parts of the dendrites given off by giant cells. On the other hand, small terminals also predominated on the main stem dendrites in roughly the same proportion as on the cell perikarya.

The ratio of axo-dendritic to axo-somatic synapses calculated per unit length of the cytomembrane had decreased, apparently owing to the increased number of the latter. There was no noteworthy rise in number of axo-dendritic synapses. These were about twice as numerous as the axo-somatic synapses, calculated per unit length of the cytomembrane. Small axon terminals surrounded numerous dendrites.

Axo-axonal synapses

The axons of various sizes crossing each other more distantly in the neuropil frequently formed synaptic interconnections. Both small and large axons made numerous synaptic contacts. The length of the synaptic zones varied from 0.3–1.0 μ.

Small axons, close to neuronal cell bodies, also synapsed on preterminal large axon terminals. These synapses differed from the above-mentioned ones only with regard to their shorter synaptic zone.

The axo-axonal synapses on the axon hillock region formed a separate group. The axon hillock and initial segment of a giant cell were surrounded by the same kind of axon terminals with regard to shape, size and content as the remainder of the cytomembrane (Fig. 9). Most of them were small, but some could be classified as

Fig. 9. – Electron micrograph showing the axon of giant neuron in the lateral vestibular nucleus [4-day-old rat. The well developed endoplasmic reticulum of the giant neuron does not extend into the axon hillock. Numerous axon terminals [rious sizes synapse on both the axon hillock (AH) and the cytomembrane of the initial segment (IS). T light glial cells are seen. At this age their processes are few in number. × 8000

All synapses on the small neurons were small. The number varied from 0–5 per cell figure.

In longitudinal sections the large axon terminals measured 2.5–1 0 μ in length and 0.5–1 2 μ in diameter Their size had doubled Most synaptic vesicles were agranular but 1–2 vesicles occurred in almost half of the terminals. The majority of the large axon terminals contained 1–3 mitochondria There were usually 1–3 junctional zones per terminal Their maximum length was 0.5 μ Desmosomal junctions, measuring 0 4–0 6 μ in length, were also seen in most large endings.

Slender axon terminals did not synapse on the cell bodies in this age group either The diameter of the small axon terminals was less than 1.5 μ usually varying between 0.5 and 1 0 μ The active zone of the small axon terminals was relatively straight, though mostly somewhat bulging with the convexity towards the cytomembrane The small axon terminals contained numerous agranular synaptic vesicles, but 1–4 granular vesicles were also seen per section in nearly all terminals. A few mitochondria could be seen in all the synapse types Mitochondria were rare in small terminals.

Axo-dendritic synapses

The axon terminals synapsing on dendrites were identical with the axonal endings synapsing on neuronal cell bodies with regard to shape structure and size. Synaptic slender terminals of both types were also regularly seen The type of axon terminal synapsing on a dendrite bore no relationship to the size of the neuron from which the dendrite originated both large and slender terminals also synapsed on the dendrites originating from small neurons. However most numerous were the synaptic axon terminals on the proximal parts of the dendrites given off by giant cells. On the other hand, small terminals also predominated on the main stem dendrites in roughly the same proportion as on the cell perikarya.

The ratio of axo-dendritic to axo-somatic synapses calculated per unit length of the cytomembrane had decreased apparently owing to the increased number of the latter There was no noteworthy rise in number of axo-dendritic synapses. These were about twice as numerous as the axo-somatic synapses, calculated per unit length of the cytomembrane. Small axon terminals surrounded numerous dendrites.

Axo-axonal synapses

The axons of various sizes crossing each other more distantly in the neuropil frequently formed synaptic interconnections. Both small and large axons made numerous synaptic contacts The length of the synaptic zones varied from 0 3–1 0 μ

Small axons, close to neuronal cell bodies also synapsed on preterminal large axon terminals. These synapses differed from the above-mentioned ones only with regard to their shorter synaptic zone

The axo-axonal synapses on the axon hillock region formed a separate group The axon hillock and initial segment of a giant cell were surrounded by the same kind of axon terminals with regard to shape size and contents as the remainder of the cytomembrane (Fig 9) Most of them were small but some could be classified as

Fig. 11. — Electron micrograph of the lateral vestibular nucleus of a 4-day-old rat. A dark glial cell of the oligodendrocyte line is seen close to a giant neuron, although separated from it by a process coming from a neighbouring dark glial cell. × 8 000

even darker than the nucleus and contained an abundance of filled rough endoplasmic reticulum tubules, Golgi membranes, free ribosomes or polyribosomes, sharply defined mitochondria and numerous Golgi cisterns. The other type of dark glial cell (Fig. 11) resembled the former to a considerable degree. In some of these cells the nucleus was even darker than the cytoplasm and often triangular in shape. These nuclei were very rich in chromatin, often containing chromatin clumps. A common feature of both these cells was that they very rarely sent out short processes.

Generally only the moderately staining nuclei of the light glial cells were identified in the light microscope. They were mostly ovoid or pea-shaped, lobulated, relatively broad and had an eccentric, hardly distinguishable nucleolus (Fig. 6). The surface area of the nucleus alone was usually larger than the area of the majority of the dark glial cells. The light glial cells were often located close to neurons and were more numerous than before.

On the fine structural level the light glial cells (Fig. 12) were all very like each other. They differed mainly with regard to shape and size (6—15 μ). The nuclear chromatin was scanty and uniformly distributed. The eccentric nucleolus was indistinct in outline. The cytoplasm, which was mostly rather scanty, contained only few organelles. The rough endoplasmic reticulum and free ribosomes, sometimes forming clusters, were seen. The mitochondria were large and smooth in appearance

Fig 10 — Electron microscopic view of a dark glial cell in the neuropil of the lateral vestibular nucleus of [illegible]-day-old rat *representing the highest degree of maturation seen in* cells of the oligodendrocytic line at this age. The *cytoplasm contains an abundance of* filled rough endoplasmic reticulum tubules, Golgi membranes, both clustered and free ribosomes and sharply defined mitochondria. × 8000

large axon terminals. The synaptic zones were usually short and the endings lay close to each other. They synapsed on both the axon hillock and the initial segment. They contained only a few cell organelles; their main content consisted of agranular synaptic vesicles, even if a few granular synaptic vesicles were present.

NEUROGLIA

The dark glial cells were readily distinguished. The dark staining nucleus was spherical or elongated and had a clearly discernible centrally placed dark nucleolus (Fig. 6). *The cytoplasm was very abundant and stained intensively with toluidine blue.* Numerous single cells occurred everywhere in the neuropil but groups of 5—I were also seen.

The size of the dark glial cells varied from 5—15 μ. These cells were of two different types and had a heavily staining cytoplasm. They had an almost spherical nucleus, containing relatively abundant, uniformly dispersed chromatin, which lined the nuclear membrane as a denser band (Fig. 10). The cytoplasm was sometimes

Fig 12 — Electron micrograph showing a typical light glial cell in the lateral vestibular nucleus of a 14-day-old rat. Fig. 14. – Light micrograph of the rostroventral part of the lateral vestibular nucleus of 7-day-old rat. Nissl bodies uniformly dispersed in the cytoplasm of giant neurons are clearly seen. The Nissl substance is abundant in the larger neurons, and in the giant neurons it also extends into the large nuclear indentations. Numerous glial cells are seen in the neuropil. The cells of the oligodendrocytic (small arrow) and astrocytic lines (big arrow) differ more clearly than before. Myelinated nerve fibres are also generally seen in this part of the nucleus. Toluidine blue stained Epon-Araldite section. × 400.

SYNAPSES

Axo-somatic synapses

The number of synapses per giant cell figure had increased to 21–30. Especially the amount of small synapses had increased to over two thirds of the total. The appearance of slender terminals contributed to the total increase. Large synapses were about twice as numerous as the slender ones, numbering 3–5 (Table I).

The total number of synapses on the medium-sized neurons was 10–16. Small synapses predominated (about 10) and the number of large terminals was under 5 per cell figure. Moreover 1 or 2 slender terminals could be seen.

Seven Day Old Rats

GENERAL FEATURES

The total cell population was relatively high, mainly owing to the abundance of glial cells (Fig 14) The various glial cells were located close to the neuronal soma, but they also occurred in more distant areas of the neuropil where they had a tendency to form groups of a few cells. All the different cells were advanced in differentiation they had a more mature appearance and the morphological details were more clearly discernible Both the dark and light glial cells were about equally numerous Myelination had also advanced throughout the lateral vestibular nucleus partially or fully myelinated thick axons were encountered everywhere. Som of these axons were of medium calibre (0.5–1.5 μ) Most of the neuropil was occupied by unmyelinated nerve fibres of various sizes. A relatively small proportion of the fibres were myelinated axons, occurring in all parts of the lateral vestibular nucleus and coursing in all directions. The number of small capillaries had increased.

NEURONS

The size and shape of the nuclei were the same as at previous stages except that in the giant neurons, in particular nuclear indentations were very numerous and extensive, reaching often as far as the nucleolus and containing cell organelles in greater number than previously The Nissl bodies appeared distinctively stained and evenly dispersed throughout the cytoplasm particularly in the giant and medium sized neurons. For the first time the Nissl substance appeared to be well organized. Centrally Nissl bodies occurred in the largest of the nuclear indentations. In the smaller neurons the amount and dispersion of the Nissl substance were considerably more variable. The division of the neurons into three groups was clearer than before because of a further increase in size of the largest neurons. The fine structure of the giant (25–40 μ) and medium sized (15–30 μ) neurons was more similar than in foregoing age groups. The fine structural examination revealed that the rough endoplasmic tubules with clusters of ribosomes were fully organized with an adult appearance of parallel cisterns. These areas were uniformly distributed throughout the cytoplasm in both the giant (Fig 15) and medium-sized neurons. Between the well organized cisterns there were neurofilaments and microtubules. In the giant neurons these areas sometimes lined the peripheral cytoplasm as a narrow band Other cell organelles, such as mitochondria and Golgi membranes with occasional granular vesicles (Fig 16) were concentrated in the zones occupied by neuroplasmic filaments. Microtubules also occurred in relative abundance in the same area The mitochondria were numerous smooth in appearance and varied from 0 4–2.5 μ in length and from 0.5–0 5 μ in diameter Both mitochondria and neurofilaments were most numerous in the giant and medium-sized neurons. Thorns were frequent on the cytomembranes of the giant neurons and the proximal parts of the dendrites. Glycogen granules, lysosomes, cytoplasmic inclusions or cilia were not seen. The cytoplasm was still primitive in appearance in the small neurons.

In the giant neurons these areas sometimes lined the peripheral cytoplasm as a narrow band Other cell organelles, such as mitochondria and Golgi membranes with occasional granular vesicles (Fig 16) were concentrated in the zones occupied by neuroplasmic filaments. Microtubules also occurred in relative abundance in the same areas. The mitochondria were numerous smooth in appearance and varied from 0 1–2.5 μ in length and from 0.5–0 5 μ in diameter Both mitochondria and neurofilaments were most numerous in the giant and medium-sized neurons. Thorns were frequent on the cytomembranes of the giant neurons and the proximal parts of the dendrites. Glycogen granules, lysosomes, cytoplasmic inclusions or cilia were not seen The cytoplasm was still primitive in appearance in the small neurons.

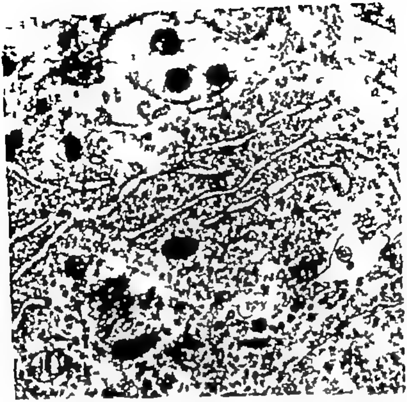

Fig. 16. – Electron micrograph of the cytoplasm of a medium-sized neuron in the lateral vestibular nucleus of a 7-day-old rat. The long arrow: endoplasmic reticulum tubules with surrounding rosettes of ribosomes are well organized. The Golgi apparatus is surrounded by granular vesicles, marked by arrow. × 20 000.

Only 0–3 small synapses were seen on the small neurons.

The large axon terminals were ovoid to elongated, 5.0–6.0 μ in length and 0.8–1.5 μ in width (Fig. 15). Double synapses occurred, synaptic contact being also established with an adjacent dendrite. The large nerve endings were sometimes impressed into the cell body (Fig. 18). The nerve endings mainly contained agranular synaptic vesicles and 2–6 mitochondria. Granular synaptic vesicles were rare.

There was usually only one active zone, though 2–3 were seen in some synapses. Their length was less than 0.5 μ. Desmosomal junctions were also frequent.

The slender axon terminals measured 5.0–7.5 μ in length and 0.4–0.8 μ in width. There were 3–5 active zones 0.2–0.4 μ long in these synapses. Desmosomal junctions were rarely identified. Agranular synaptic vesicles were often seen close to the active zones and many endings also contained 1–2 granular vesicles. Mitochondria seemed to be very numerous.

The diameter of the small axon terminals varied from 0.6 μ – 2.5 μ and their synaptic junction was 0.4–2.0 μ. The small ending was sometimes impressed into the cell body and occasionally a thorn originating from the neuron was impressed into the terminal. The synaptic vesicles were mainly agranular but about one third of the small axon terminals also contained 1–2 granular vesicles, and 1–2 mitochondria were frequently seen.

NEUROGLIA

Small dark glial cells were identified by their heavily staining spherical to elongated nuclei with prominent chromatin and 1–4 nucleoli (Fig. 14). Their scanty cytoplasm was also intensely stained. They still had a tendency to occur in groups of 2–5, often in contact with each other throughout the neuropil and frequently adjacent to the capillaries.

These cells were in general considerably more alike and more mature than in the foregoing age groups, although more primitive cells also occurred. The size of the cells varied from 5–13 μ and they had only few short processes. The chromatin was relatively uniformly distributed throughout the nucleoplasm, except close to the nuclear envelope which was lined by a narrow band of condensed chromatin. The rough endoplasmic reticulum tubules and the Golgi cisterns were mostly disposed in parallel array. Another characteristic feature was the presence of numerous clusters of ribosomes giving the cytoplasm its dark appearance. The mitochondria were relatively sparse and small. These cells seemed to be oligodendrocytes.

The light glial cells (Fig. 15) were distinguished from the dark ones by their larger pea- or kidney-shaped, often lobulated nuclei, which stained only weakly with

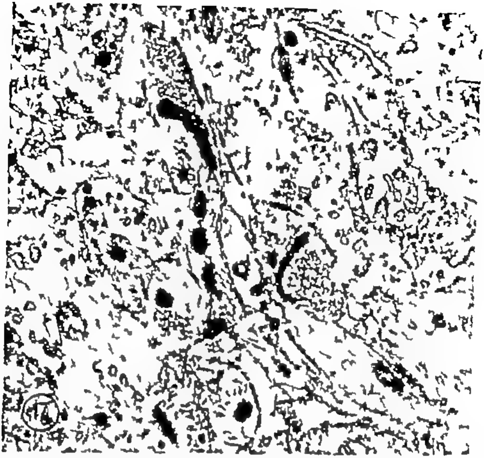

Fig. 17. — Electron micrograph showing a slender terminal with an extensive active zone synapsing on the cell body of a giant neuron in the lateral vestibular nucleus of a [illegible]-day-old rat. × 20 000

Axo-dendritic synapses

A large proportion of the neuropil was occupied by mostly very extensive dendrites, given off in great number by the giant and medium-sized neurons. The synaptic junctions were similar to the axo-somatic synapses. The number of both large and slender axo-dendritic synapses on the proximal parts of dendrites was somewhat higher at this age. Some nerve endings with only one extensive "active zone" per section synapsed on both the proximal and distal parts of the dendrites. Small terminals clearly predominated on the distal parts of the dendrites, in particular.

Axo-axonal synapses

Axo-axonal synapses were most frequent between twisting axons in the distant neuropil, though in lesser number than before. Their synaptic zones were similar to those of the small terminals. A small calibre axon sometimes synapsed on one or two adjacent axons. The preterminal small axon terminals adjacent to the neuronal cytomembranes synapsed more often than in the foregoing age groups.

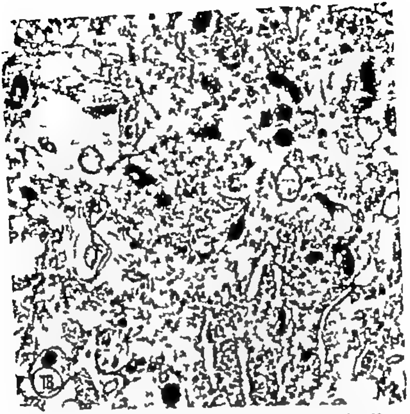

Fig. 13. – Electronmicrograph of the lateral vestibular nucleus of a 7-day-old rat, showing synapsing large terminal impressed into the cell body of a giant neuron. At this age the large axon terminals contained a large amount of agranular synaptic vesicles. × 20 000.

NEUROGLIA

Small dark glial cells were identified by their heavily staining spherical to elongated nuclei with prominent chromatin and 1–4 nucleoli (Fig. 14). Their scanty cytoplasm was also intensely stained. They still had a tendency to occur in groups of 2–5, often in contact with each other throughout the neuropil and frequently adjacent to the capillaries.

These cells were in general considerably more alike and more mature than in the foregoing age groups, although more primitive cells also occurred. The size of the cells varied from 5–13 μ and they had only few short processes. The chromatin was relatively uniformly distributed throughout the nucleoplasm, except close to the nuclear envelope which was lined by a narrow band of condensed chromatin. The rough endoplasmic reticulum tubules and the Golgi cisterns were mostly disposed in parallel array. Another characteristic feature was the presence of numerous clusters of ribosomes giving the cytoplasm its dark appearance. The mitochondria were relatively sparse and small. These cells seemed to be oligodendrocytes.

The light glial cells (Fig. 15) were distinguished from the dark ones by their larger pear- or kidney-shaped, often lobulated nuclei, which stained only weakly with

toluidine blue. Only the nuclear membrane stained more heavily. The diameter measured 6—17 μ. These cells were not pleomorphic. They had one or two nucleoli which were lobulated and smooth in appearance. The chromatin was usually uniformly distributed, although globular chromatin aggregates were sometimes located anywhere in the nucleoplasm. The cytoplasm rarely stained heavily enough to stand out against the background in light microscopy. With the electron microscope the cytoplasm was seen sending out variously shaped thin processes between the surrounding structures. These processes contained only a few cytoplasmic organelles. The slender processes of these cells were also more abundant than before and more often extended to the vicinity of neurons, although they were only occasionally apposed to their cytomembranes. The tubules of rough endoplasmic reticulum were short and often contained floccular material. The Golgi cisterns were flat and the mitochondria long, plump and inconspicuous. Glio-filaments in parallel array were sometimes seen in the cytoplasm. The light glial cells sometimes formed groups of 2—4 and usually occurred close to neurons being satellites to them more often than the dark glial cells. These cells thus resembled astrocytes with regard to both structure and location.

Ten Day Old Rats

GENERAL FEATURES

In the light microscope the general appearance of the neuropil was very dark in tone and the various structures and their details were quite well distinguished (Fig. 19). A clear organization of the details was characteristic of the internal structure of both the neurons and the glial cells. Among the neurons the giant cells showed an increasing differentiation into a separate group as regards both size and shape. The division of the glial cells into oligodendrocytes and astrocytes had also become more pronounced. Areas were forming in the neuropil in which strongly myelinated nerve fibres predominated and other structures were infrequent. Besides myelinated axons, these areas contained unmyelinated fibres, dark glial cells and occasional small neurons. These strongly myelinated areas were surrounded by neuropil showing much less advanced myelination. This part of the neuropil contained neurons and glial cells in striking abundance; groups of 3—4 neurons in contact with one another occurred.

In the electron microscope, too, most of the neuropil was occupied by myelinated fibres varying in calibre, although the majority were thick (1.5—2.5 μ). Completely myelinated areas did not occur; even in the most heavily myelinated areas unmyelinated fibres were also relatively frequent, although they were in the minority. Myelination was more abundant than before in the immediate vicinity of neurons. Early myelination figures were considerably more common than advanced stages. As a rule the axons at an advanced stage of myelination were of large calibre and they never seemed to extend as far as the cytomembrane. However unmyelinated axons were in majority in the neighbourhood of the neuronal bodies and the proximal part

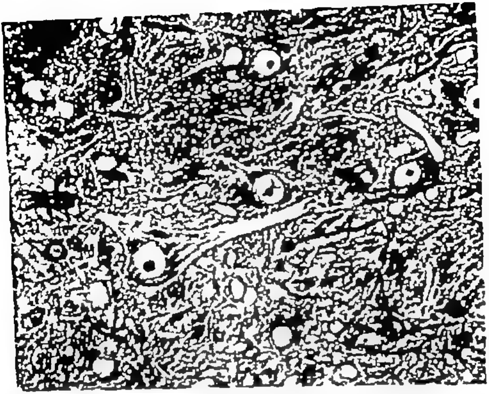

Fig. 19. — Light micrograph of the rostroventral part of the lateral vestibular nucleus of a 10-day-old rat. Well organized Nissl bodies are seen in the cytoplasm of giant neurons, and structural details are clearly distinguished in the smaller neurons also. Relatively mature forms occur among both the astrocytic (big arrows) and oligodendrocytic (small arrows) glial cells. Advanced myelination is seen in the neuropil round nerve fibres of [illegible] calibres, but not to an appreciable extent in the neighbourhood of neurons. Toluidine blue stained Epon-Araldit section. × 400.

of the dendrites. Although unmyelinated nerve fibres had become considerably less frequent, they occurred everywhere and were usually small in calibre. A considerable steadily increasing proportion of the neuropil surrounding the neurons was occupied by dendrites. Glial processes varying in shape were seen everywhere between other structures. In many places they extended as far as the cytomembranes of neurons, in other sites they continued as narrow projections insinuating themselves between the larger axon terminals and the cytomembrane.

NEURONS

The largest of the giant neurons showed the same features that were typical of these cells at the older stage. Their multipolar isodendritic nature was more obvious than before. The same characteristic features were also more accentuated in the medium sized neurons (15—30 μ).

The Nissl bodies formed relatively extensive, organized, often spindle-shaped areas, separated from each other and from the cell membrane by pale areas. This feature was conspicuous in the giant cells and also in many medium-sized neurons. In the

small neurons the cytoplasm was scanty and the details were not readily distinguished in the light microscope

The size of the neurons had remained unchanged except that a slight increase was noted in the giant cells (25–45 μ) The diameter of the small neurons varied from 10–20 μ The size shape and structure of the nuclei had remained unchanged Nuclear indentations were seen in neurons of all sizes, but they were smaller and fewer in the giant neurons than at the foregoing age.

In the electron microscope the general picture of the cytoplasm was very much the same as in the foregoing age group with regard to the number distribution and structural details of the organelles In the giant neurons extensive, well organized areas of rough endoplasmic reticulum were separated by expanding distinct areas occupied by neurofibrils and microtubules, in which the neurofilaments were disposed in parallel bundles. In many giant neurons these areas also separated the rough endoplasmic reticulum from the cytomembrane and continued into the dendrites as expanding massive zones. In the medium-sized neurons areas consisting of neurofilaments and microtubules alone were infrequent, and in the small neurons they were entirely missing

The *cytoplasm of the small neurons had also changed. Rough endoplasmic reticulum* tubules in parallel array were seen although the tubules were still rather short, thick and clumsy Cytoplasm primitive in appearance and lacking organization also occurred however

Mitochondria varying in length from 0.5–4 0 μ were generally found in the same areas in the cytoplasm as the neurofibrils. The mitochondria were very numerous. Subsurface cisterns occurred in the cytoplasmic membranes of the small and medium sized neurons. *Lysosomes, measuring 0 4–0 5 μ in diameter appeared for the first* time in the giant cells, usually in small groups. They were smoothly spherical in shape and the interior was dense and homogeneous. Moreover in thi age group cilia were observed for the first time on the cytomembranes of the smaller neurons. Small thorns, sometimes extending into the large terminals, were a common finding

SYNAPSES

Axo-somatic synapses

The total number of axon terminals synapsing on giant neuron figures varied from 21–34 (Table I) There were usually 4–6 large terminals and 2–5 slender ones per giant cell profile the remainder being small terminals The number of synapsing terminals per medium-sized neuron figure had risen mainly owing to an increase in small terminals. The total number of synapsing terminals per neuron profile was 14–21 Of these, only 1–3 were large Moreover 1–2 slender terminals synapsed on most medium-sized cells.

Furthermore slender terminals with an extensive active zone synapsed on some giant and medium sized neurons In the small neurons only small axon terminals occurred in a number of 0–4 per cell figure

The size of th large axon terminals aried from 3–7 μ in longitud nal sections and from 1 4–2 5 μ in diam t r With regard to both ize and shape the large a on terminals resembled th e corresponding adu lt structures (Fig 20) The terminals were

Fig. 20. – Electron micrograph of the lateral vestibular nucleus of 10-day-old rat, showing a typical large axon terminal between two neurons synapsing on both the giant neuron above and the perikaryonal surface of the medium-sized neuron seen below. Desmosomal junctions (arrow) are also seen between the large terminal and the neuronal cytomembrane of the giant neuron. Also a typical small axon terminal synapses on the cell body of giant neuron. × 20 000

to a great extent filled with agranular synaptic vesicles. Mitochondria also occurred in abundance, mostly 5–6 per terminal, but even 10 per terminal were observed. Granular synaptic vesicles were infrequent. Active zones were a common finding, the average being 3–4 per terminal. They usually measured 0.3–0.4 μ in length. Desmosomal junctions, measuring 0.4–0.6 μ in length, were seen (1–3) in most of the large terminals.

The slender axon terminals varied from 4–10 μ in length and from 0.4–1.5 μ in diameter although the diameter seldom exceeded 1 μ. There were 3–9 active zones per terminal profile varying in length from 0.4–0.8 μ (Fig. 21). Desmosomal junctions were rare. The slender axon terminals very often synapsed on surrounding dendrites. They contained abundant mitochondria, varying in number within the same range as in the large terminals. Otherwise their content was the same as in the foregoing age group. The size and content of the small axon terminals was the same as in the foregoing age group (Fig. 22). The variation in shape of the synaptic zone also corresponded to the previous findings. The maximum length was 1.5 μ. The number of mitochondria sometimes rose to 5–6 per terminal profile.

small neurons the cytoplasm was scanty and the details were not readily distinguished in the light microscope

The size of the neurons had remained unchanged except that a slight increase was noted in the giant cells (25—45 μ) The diameter of the small neurons varied from 10—20 μ. The size, shape and structure of the nuclei had remained unchanged Nuclear indentations were seen in neurons of all sizes, but they were smaller and fewer in the giant neurons than at the foregoing age.

In the electron microscope the general picture of the cytoplasm was very much the same as in the foregoing age group with regard to the number distribution and structural details of the organelles In the giant neurons extensive, well organized areas of rough endoplasmic reticulum were separated by expanding distinct areas occupied by neurofibrils and microtubules, in which the neurofilaments were disposed in parallel bundles In many giant neurons these areas also separated the rough endoplasmic reticulum from the cytomembrane and continued into the dendrites as expanding massive zones. In the medium-sized neurons areas consisting of neurofilaments and microtubules alone were infrequent and in the small neurons they were entirely missing

The cytoplasm of the small neurons had also changed Rough endoplasmic reticulum tubules in parallel array were seen although the tubules were still rather short, thick and clumsy Cytoplasm primitive in appearance and lacking organization also occurred, however

Mitochondria varying in length from 0.5—1 0 μ were generally found in the same areas in the cytoplasm as the neurofibrils. The mitochondria were very numerous. Subsurface cisterns occurred in the cytoplasmic membranes of the small and medium sized neurons Lysosomes, measuring 0 4—0 5 μ in diameter appeared for the first time in the giant cells, usually in small groups. They were smoothly spherical in shape and the interior was dense and homogeneous. Moreover in this age group cilia were observed for the first time on the cytomembranes of the smaller neurons. Small thorns, sometimes extending into the large terminals, were a common finding

SYNAPSES

Axo-somatic synapses

The total number of axon terminals synapsing on giant neuron figures varied from 21—34 (Table I) There were usually 4—6 large terminals and 2—5 slender ones per giant cell profile the remainder being small terminals The number of synapsing terminals per medium-sized neuron figure had risen, mainly owing to an increase in small terminals The total number of synapsing terminals per neuron profile was 14—21 Of these, only 1—3 were large Moreover 1—2 slender terminals synapsed on most medium-sized cells.

Furthermore slender terminals with an extensive active zone synapsed on some giant and medium sized neurons. In the small neurons only small axon terminals occurred in a number of 0—4 per cell figure

The size of the large axon terminals varied from 3—7 μ in longitudinal sections and from 1 4—2 5 μ in diameter With regard to both size and shape the large axon terminals resembled the corresponding adult structures (Fig 20) The terminals were

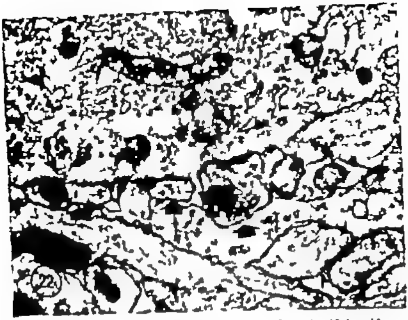

Fig. 22. — Electron micrograph of the lateral vestibular nucleus of 10-day-old rat, showing three small synapsing axon terminals (thick arrows) on the cell body of a giant neuron. × 20 000

synapses were most often seen in the vicinity of neurons. Small axon terminals synapsed on large ones in increasing number in these sites, and the large axon terminals in turn synapsed on the perikarya of the giant and medium-sized neurons or on their dendritic main stems.

NEUROGLIA

The oligodendrocytes were relatively uniform in appearance (Fig. 19) in the light microscope. Both the nucleus and the cytoplasm stained with toluidine blue; the outlines of both were therefore distinct. The nucleus also stained more heavily than in any other kind of cell. Nonetheless, 1–2 nucleoli were quite conspicuous. Many of these cells were located in myelinated areas, although they also occurred in the neighbourhood of neurons. They were single or occurred in groups of 2–5. This cell type had obviously increased in number compared with the foregoing age and clearly predominated among the glial cells. The cell profiles of the oligodendrocytes varied in size from 5–15 µ. These cells were mostly readily distinguished as a separate group by the electron density of their cytoplasm, which was always more pronounced than in other glial cells. However, there was a considerable individual variation with regard to the general appearance of both the nucleus and, especially, the cytoplasm. The majority of these cells resembled the more mature forms described in the foregoing age group. They had an ovoid nucleus containing an abundance of chromatin, often forming clumps close to the nuclear envelope. The cytoplasm contained sparse rough endoplasmic reticulum and numerous ribosomes, both free and in clusters. In addition, the free cytoplasm contained an abundance of fine particulate material, vesicles of

Fig 21 — Electron micrograph of the lateral vestibular nucleus of a 10-day-old rat. A slender terminal with numerous active zones synapses on the cell body of a giant neuron. A glial cell of the astrocytic line is in satellite position to the giant neuron. × 20 000

Axo-dendritic synapses

The proximal parts of the dendrites of all neurons contained various synapsing terminals in similar numbers and no morphological differences were observed between the dendrites originating from neurons of different sizes. Morphologically different terminals synapsed on the dendrites in approximately the same proportion as they did on the largest neurons although their total amount was somewhat greater on the proximal parts of the dendrites than on the cell bodies. The terminals synapsing on the main stem dendrites were mostly small. Furthermore dendritic thorns occurred in great number on the proximal parts of the dendrites. These thorns were usually in synaptic contact with many terminals; they also formed long synaptic zones when penetrating into the interior of the larger axon terminal. In addition the large and slender terminals primarily synapsing on the proximal parts of the dendrites also synapsed on one or two smaller adjacent dendrites more often than before.

Axo-axonal synapses

Axo-axonal synapses more distantly in the neuropil were rare. Complex axo-dendritic structures such as lateral vestibular glomeruli were not encountered. Axo-axonal

Fig. 21. — Light micrograph of a transverse section from the dorsocaudal part of the lateral vestibular nucleus of 20-day-old rat. Myelin is abundant also in the vicinity of neurons, and numerous capillaries are seen. The myelinated bundles of nerve fibres of large calibre are probably cerebello-vestibular fibres entering the nucleus. Toluidine blue stained Epon-Araldite section. × 400.

tensive and in general uniformly distributed throughout the cytoplasm, except for a narrow border at the cytomembrane, which was free of them (Fig. 24). Together with Golgi membranes they also penetrated into the proximal parts of the dendrites in massive bands. Parallel tubules of rough endoplasmic reticulum were more seldom seen; they were mostly curved and frequently anastomosing. They were surrounded by abundant rosettes mostly of 4–6 ribosomes. The areas of rough endoplasmic reticulum were everywhere separated from one another by zones occupied by neurofilaments and microtubules. In the giant neurons, in particular, these areas separated the Nissl bodies from the cytomembrane as a narrow rim and continued as a broadening band towards the dendrites. Neurofilaments generally predominated in these areas. The neurofibrils and microtubules were often disposed in parallel bundles, but mostly they seemed to swirl and stream round the Nissl bodies. Golgi cisterns occurred in great number, sometimes scattered over the cytoplasm, but most often located in the perinuclear area. They were always surrounded by numerous vesicles of various sizes and multivesicular bodies. Some of these vesicles were coated, but the majority were alveolate. Large granular vesicles were also common.

various sizes and bulging Golgi cisterns. The mitochondria were small and usually displayed longitudinal cristae.

In the astrocytes only the large spheroid kidney- or pear-shaped light nucleus containing one or more small nucleoli was clearly discernible (Fig. 19). The cytoplasm, which only occasionally could be identified in the light microscope, was scanty and stained weakly. With regard to size and shape these cells often resembled small neurons, although they could be identified in the light microscope owing to the fact that the neurons had a larger nucleolus and a larger and more heavily staining cytoplasm. The light glial cells were mostly located in the unmyelinated areas of the neuropil, usually close to neurons. They were satellites of neurons. In places they occurred in groups of 2—3.

The size of the astrocytes varied from 5—17 μ per cell profile. In the electron microscope they formed a very homogeneous group, greatly resembling the corresponding cells in the foregoing age group. The chromatin was usually uniformly distributed in the nucleus, which was often elongated or spherical. The cytoplasm appeared to be less lucent than previously. The rough endoplasmic reticulum tubules were long and often contained floccular material. The most conspicuous feature of the astrocytes was the great number of ribosomes, which, however, varied from cell to cell. The mitochondria were plump and long. All these cells sent out numerous, often very thin processes.

Twenty Day Old Rats

GENERAL FEATURES

The most conspicuous feature at this age was a markedly increased myelination of previously poorly myelinated areas (Fig. 25). Bundles composed of numerous, mostly thick and quite strongly myelinated axons dominated the general picture of the lateral vestibular nucleus. The smaller axons also seemed to be generally involved by the process of myelination. The neurons were often surrounded by a network of small axons at an early stage of myelination. The distribution of neurons of various sizes, their size and structural details in the light microscope did not differ appreciably from the findings in the previous age group. An abundant occurrence of small capillaries was also observed. On the fine structural level the larger axons (1.5—2.5 μ) close to neurons were also generally myelinated. The thickest of the myelinated fibres often touched the neuronal cytomembranes.

The large axon terminals were for the first time seen to originate from small myelinated axons, although this was not a frequent finding. Unmyelinated fibres occupied a relatively small proportion of the total area. They were mainly located close to neurons. The unmyelinated axons measured 0 [illegible] μ in diameter.

NEURONS

The shape, size and structure of the nuclei remained the same as before. In the giant neurons (25—50 μ) the rough endoplasmic reticulum tubules were relatively inex

Fig. 25 — High power electron micrograph of subsurface cistern (arrow) on the neuronal surface of giant neuron in Deiters nucleus of 20-day-old rat. × 40 000

The mitochondria were in general uniformly distributed over the cytoplasm although they clearly avoided areas occupied by rough endoplasmic reticulum and ribosomes. They were usually small, with a maxim m length of 2–3 µ. Most of the mitochondria had longitudinally oriented cristae. Lysosomes were a frequent finding in the giant neurons. Structurally they did not differ from those previously described. Stacks of several closely pposed cisterns and glia were also more common in the smaller neurons. Thorns were regular finding and their content was the same as previously described. They were ften in synaptic contact with 2–3 small axon terminals. Distinct zones mainly occupied by neurofibrils were also seen in the medium-sized neurons. In the small neurons, too, the rough endoplasmic reticulum t bules were narrower and longer than previously and to some extent topographically organized. Subsurface cisterns (Fig. 25) were regularly seen, but no cytoplasmic inclusions were encountered.

SYNAPSES

Axo-somatic synapses

The total number of synapsing terminals per giant cell profile aried from 16–28. The umber of morphologically different synapsing axon terminals per neuron figure was f the same order as in the foregoing age group (T ble I).

The total number of synapsing axon terminals varied from 10–16 per cross-section of medium-sized neuron, being on average nearer the former number. The distribution of morphologically different synapsing axon terminal per neuron figure was of the same order as before.

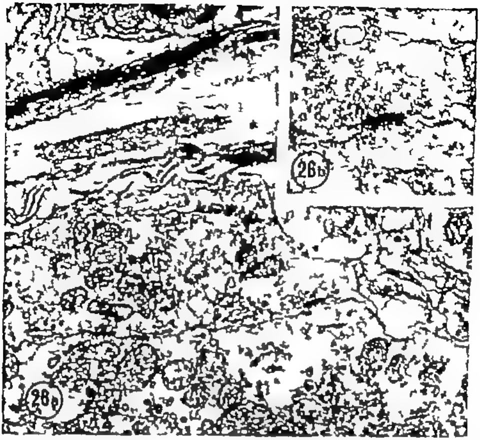

Fig. 26 a. — Electron micrograph showing a large axon terminal on the cell body of a giant neuron. Besides the usual active zone a desmosome-like junction is seen, which resembles a gap junction. A small axonal ending is also in synaptic contact with the large axon terminal. × 20 000.

b. — Higher magnification of the junction resembling a gap junction. The close membrane apposition of this kind usually is a sign of electrical coupling. × 40 000.

There was no change in number of synaptic small endings per small neuron figure compared with the foregoing age groups.

Large axon terminals were similar in shape, size and contents to the corresponding structures in the foregoing age group which they also resembled with regard to synaptic zones. The only exception was a desmosome-like junction (Fig. 26 a and b) resembling a "gap junction" in which the opposing cell membranes converged, thus producing a narrow cleft. It measured 0.25 μ in length, and the very narrow synaptic cleft was filled with electron dense material. The size, shape and contents of the slender axon terminals were largely the same as in the foregoing age group. In general, the size, shape and contents of the small axon terminals, also were the same as in the foregoing age group. Agranular synaptic vesicles were common, occurring usually in a number of 1—5 per terminal.

Axo-dendritic synapses

There was no change compared with the foregoing age group.

Axo-axonal synapses

These synapses were mostly observed close to the neuronal cell bodies or dendrites and were most numerous in the locations where unmyelinated nerve fibres were in

the majority Most axo-axonal synapses consisted of small terminals synapsing on large axon terminals, which were themselves presynapti to the neuronal cell body or the main dendritic stem Moreover adjacent axons sometimes synapsed on one another and also on adjacent dendrites (Fig 27).

NEUROGLIA

Among the glial cells oligodendrocytes were more numerous than astrocytes A con siderable proportion of the f rmer were located in the areas of myelinated fibres or in groups of 5–6 close to capillaries Th astrocytes were usually situated in the vicinity f neurons, mostly single, though sometimes in groups of 2–3 The total number f glial cells seemed to be higher than before owing to an increase in the oligodendrocytes

Both broad and slender astrocytic processes insinuated themsel es in increasing numbers between the terminals into contact with the cytomembranes. The broad processes ften contained bundles of astrocytic filaments, in places lining the cytomembrane for long distances. These structures were most numerous round the large terminals, while the small terminals often lay so close to each ther on the cytomembrane that not even ery slender projections could penetrate between them.

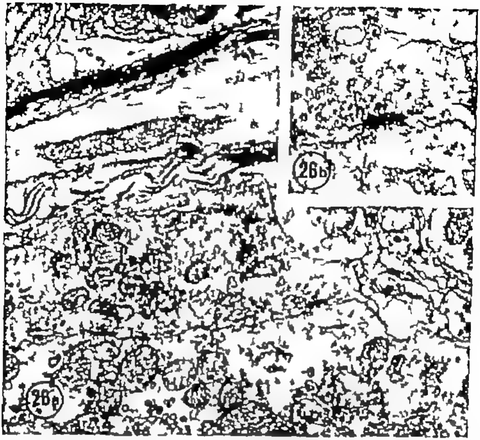

Fig. 26 a. — Electron micrograph showing a large axon terminal on the cell body of a giant neuron. Besides the usual active zone, a desmosome-like junction is seen, which resembles a gap junction. A small axonal ending is also in synaptic contact with the large axon terminal. × 20 000.

b. — Higher magnification of the junction resembling a "gap junction". The close membrane apposition of this kind usually is a sign of electrical coupling. × 10 000.

There was no change in number of synaptic small endings per small neuron figure compared with the foregoing age groups.

Large axon terminals were similar in shape, size and contents to the corresponding structures in the foregoing age group, which they also resembled with regard to synaptic zones. The only exception was a desmosome-like junction (Fig. 26 a and b) resembling a "gap junction" in which the opposing cell membranes converged, thus producing a narrow cleft. It measured 0.25 μ in length, and the very narrow synaptic cleft was filled with electron dense material. The size, shape and contents of the slender axon terminals were largely the same as in the foregoing age group. In general, the size, shape and contents of the small axon terminals, also, were the same as in the foregoing age group. Agranular synaptic vesicles were common, occurring usually in a number of 1—5 per terminal.

Axo-dendritic synapses

tubules were often somewhat flattened and obviously lined by fine granular material.

One clearly distended axon terminal seen close to the cytomembrane of a giant cell attracted attention (Fig. 34). It differed clearly from other terminals by the presence of 1–2 centrally located lysosomes surrounded by large granular vesicles. In other respects it resembled the adjacent axon terminals.

NEURONS

On the whole the fine structural details of the neurons resembled those seen in the foregoing age group.

The large neurons varied in size from 25–55 μ, the medium-sized neurons from 15–33 μ, and the small ones from 10–20 μ.

Thirty-Day Old Rats

GENERAL FEATURES

The light microscopic picture resembled that seen at the foregoing age but on the other hand it did not differ much from the adult stage either Myelination had increased to some extent (Fig 28)

At the same time the mostly thinner fibres in the vicinity of neurons generally showed early myelination figures or were myelinated The different categories of neurons approached the adult stage with regard to size shape and content

No great changes were observed in the general appearance of the neuropil although the features previously described had become more accentuated In the neighbourhood of neurons early myelination figures were still very abundant round the smaller axons. Sometimes the large axon terminals synapsing on the cytomembranes of neurons originated from small axons at an early stage of myelination, but the majority obviously originated from unmyelinated axons. Myelinated axons of various sizes were very often apposed to the cytomembrane for long distances in neurons of all sizes. In the less myelinated areas of the neuropil, synaptic complexes formed by synapsing axons and dendrites occurred (Fig 29) resembling the lateral vestibular glomeruli.

A very conspicuous feature was the abundant occurrence of astrocytic processes, varying in shape in the vicinity of the cytomembranes (Fig 30) They also surrounded the axon terminals as slender projections. Dendritic expansions also appeared for the first time (Fig 29) It was typical of these structures that they were packed with mitochondria and often sent out numerous dendritic thorns. Some of the mitochondria were distorted and contained large amounts of glycogen granules. Moreover granular vesicles were regularly present in these expansions. Small axon terminals were frequently seen synapsing on them.

Axon terminals entirely deviating in structure from other terminals were also seen for the first time in this age group They occurred either in the non-synapsing parts of axons or synapsed on the surrounding dendrites or neurons. Mostly they appeared to be distended axon terminals, containing various unusual structures, e g abundant elongated mitochondria, the majority of which showed longitudinally oriented cristae (Fig 31) In addition, they contained granular vesicles of various sizes Bodies resembling lysosomes were also seen in these altered endings Sometimes their axoplasm contained fine granular material, causing a greater electron density Besides neurofilaments and agranular synaptic vesicles, the endings contained vesicles of various sizes.

In another type of expanded nerve ending in contact with dendrites (Fig 32) there seemed to be no or only a few synaptic vesicles adjacent to the presynaptic membrane although their structure otherwise roughly resembled that described above

A third type of terminal was also seen, characterized by the accumulation of tubular profiles, packed side by side and probably parallel sometimes filling up most of the terminal (Fig 33) The electron micrographic findings indicated that these endings could also synapse on neurons The altered ending seen in Fig 33 was larger than the remainder of the large terminals synapsing on the same giant cell. The parallel

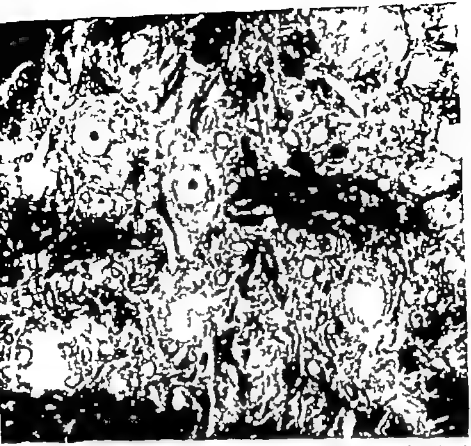

Fig. 28. — Light micrograph of the dorsocaudal part of the lateral vestibular nucleus of a [illegible]0-day old rat. SYNAPSES

Axo-somatic synapses

The total number of axon terminals synapsing on giant neuron figures was of the same order as in the foregoing age group. Their total number per giant neuron profile varied from 17–31 (Table I). Small terminals were clearly in the majority: there were only 2–4 large terminals and 1–5 slender terminals per giant neuron figure.

Fig. 34. — Electron micrograph of the lateral vestibular nucleus of a 30-day-old-rat showing an altered axon terminal, or expanded preterminal part of an axon. The difference compared to other axon terminals is that two lysosomes (marked by arrow) surrounded by granular vesicles are seen at the middle of the terminal. Granular vesicles are also rare in the large endings at this age. × 90 000.

The number of synapsing axon terminals per medium-sized neuron figure was about the same as in the foregoing age group. The majority were small terminals; there were only a few large and slender terminals per cell profile. The axo-somatic synapses of the small neurons showed no change.

With regard to shape, size, content, and synaptic zones the large axon terminals resembled the corresponding terminals at the foregoing age group. No change was observed in the structure of the slender axon terminals either. The small axon terminals were the same as in the foregoing age group, except that subsynaptic formations were regularly seen.

Axo-dendritic synapses

The axo-dendritic synapses resembled those seen at the foregoing age except that 1–2 small axon terminals generally synapsed on dendritic expansions.

Axo-axonal synapses

The only difference compared with the foregoing age was that axons and dendrites in synaptic contact with one another occasionally formed synaptic complexes. Most

often the central axon synapsed only on the surrounding dendrites, while the axons surrounding the central axon were not in synaptic contact with the latter. However in one instance a peripheral axon in a lateral [illegible]estibular glomerulus was seen to synapse on the central axon (Fig. 29).

NEUROGLIA

The glial cells were readily identified as oligodendrocytes and astrocytes. The majority of the glial cells obviously represented a high degree of maturity: less differentiated, early forms were rare. The cytoplasm and sharply defined nucleoli of the oligodendrocytes stained heavily with toluidine blue. The astrocytes stained more heavily than before. The outlines [illegible]f the cytoplasm [illegible]f the astrocytes were often quite clearly distinguished.

The astrocytes were satellites of neurons, giant cells in particular. Oligodendrocytes were very often observed in strongly myelinated areas, and when situated close to neurons, they were most frequently seen in the vicinity of medium-sized and small neurons. The oligodendrocytes constituted [illegible]bout 60 per cent of the total number of glial cells, 40 per cent thus being astrocytes.

Small capillaries were abundant, especially in the less heavily myelinated areas of the neuropil. Sometimes they surrounded even single neurons in great number.

Adult Rats

GENERAL FEATURES

The neurons of various sizes were organized into groups of 3–5 per transverse section (Fig. 55). Giant cells were considerably more numerous in the dorsocaudal part of the nucleus than in other parts. Nonetheless, medium-sized and small neurons predominated everywhere in the nucleus. The dendrites [illegible]f the giant cells ramified into the surrounding neuropil. The dendritic tree of the small neurons was less extensive. The shape of the giant and medium-sized neurons was more [illegible]ariable than that of the small neurons (Figs. 53 and 56). The former varied in shape from elongated polygonal to flask- or spindle-shaped or ovoid. The small neurons were mostly spheroid or ovoid, and they had [illegible] more extensive nucleus than the larger neurons, often occupying most of the surface area in transverse sections.

In the neuropil the process of myelination was [illegible] advanced in smaller areas close to neurons, and thus small neurons were [illegible] from each other by myelinated fibres. Bundles [illegible] large-sized [illegible] axons [illegible] the nucleus in all directions. Axons with [illegible] encountered, especially round the smaller axons. [illegible] originated from myelinated axons. The [illegible] and was found by [illegible] and scattered [illegible] axons and their branches

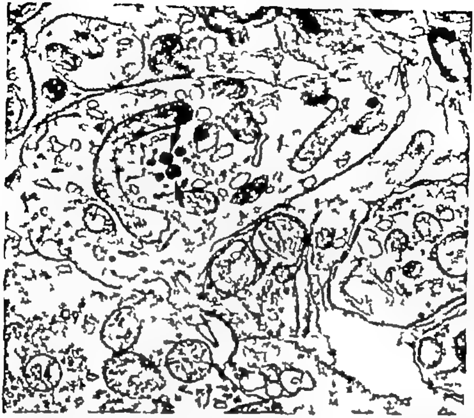

Fig. 34. — Electron micrograph of the lateral vestibular nucleus of a 30-day-old rat, showing an altered axon terminal, or expanded preterminal part of an axon. The difference compared to other axon terminals is that two lysosomes (marked by arrows) surrounded by granular vesicles are seen at the middle of the terminal. Granular vesicles are also rare in the large endings at this age. × 20 000

The number of synapsing axon terminals per medium-sized neuron figure was about the same as in the foregoing age group. The majority were small terminals; there were only a few large and slender terminals per cell profile. The axo-somatic synapses of the small neurons showed no change.

With regard to shape, size, contents and synaptic zones the large axon terminals resembled the corresponding terminals at the foregoing age group. No change was observed in the structure of the slender axon terminals, either. The small axon terminals were the same as in the foregoing age group, except that subsynaptic formations were regularly seen.

Axo-dendritic synapses

The axo-dendritic synapses resembled those seen at the foregoing age, except that 1–2 small axon terminals generally synapsed on dendritic expansions.

Axo-axonal synapses

The only difference compared with the foregoing age was that axons and dendrites in synaptic contact with one another occasionally formed synaptic complexes. Most

often the central axon synapsed only on the surrounding dendrites, while the axons surrounding the central axon were not in synaptic contact with the latter. However, in one instance a peripheral axon in a lateral vestibular glomerulus was seen to synapse on the central axon (Fig. 29).

NEUROGLIA

The glial cells were readily identified as oligodendrocytes and astrocytes. The majority of the glial cells obviously represented a high degree of maturity; less differentiated, early forms were rare. The cytoplasm and sharply defined nucleoli of the oligodendrocytes stained heavily with toluidine blue. The astrocytes stained more heavily than before. The outlines of the cytoplasm of the astrocytes were often quite clearly distinguished.

The astrocytes were satellites of neurons, giant cells in particular. Oligodendrocytes were very often observed in strongly myelinated areas, and when situated close to neurons, they were most frequently seen in the vicinity of medium-sized and small neurons. The oligodendrocytes constituted about 60 per cent of the total number of glial cells, 40 per cent thus being astrocytes.

Small capillaries were abundant, especially in the less heavily myelinated areas of the neuropil. Sometimes they surrounded even single neurons in great number.

Adult Rats

GENERAL FEATURES

The neurons of various sizes were organized into groups of 3–5 per transverse section (Fig. 35). Giant cells were considerably more numerous in the dorsocaudal part of the nucleus than in other parts. Nonetheless, medium-sized and small neurons predominated everywhere in the nucleus. The dendrites of the giant cells ramified into the surrounding neuropil. The dendritic tree of the small neurons was less extensive. The shape of the giant and medium-sized neurons was more variable than that of the small neurons (Figs. 35 and 36). The former varied in shape from elongated polygons to flask- or spindle-shaped or ovoid. The small neurons were mostly spheroid or ovoid and they had a more extensive nucleus than the larger neurons, often occupying most of the surface area in transverse sections.

In the neuropil the process of myelination was also advanced in smaller axons close to neurons, and thus single neurons were separated from each other by myelinated fibres. Bundles of large-sized myelinated axons traversed the nucleus in all directions. Axons with incomplete myelination were also encountered, especially round the smaller axons. Both slender and small terminals sometimes originated from myelinated axons. The unmyelinated part of the neuropil was scanty and scattered, and was found by a large number of dendrites, small-sized axons and their terminals

Fig. 34 — Electron micrograph of the lateral vestibular nucleus of a 30-day-old rat showing an altered axon terminal, an expanded preterminal part of an axon. The difference compared to other axon terminals is that two lysosomes (marked by arrows) surrounded by granular vesicles are seen at the middle of the terminal. Granular vesicles are also rare in the large endings at this age. × 20 000

Medium-sized neurons are most numerous in this part of the nucleus, also. Both astrocytes (large arrows) and oligodendrocytes (small arrows) are clearly distinguished. Toluidine blue stained Epon section. × 400.

NEURONS

In the giant and medium-sized neurons extensive Nissl bodies, readily distinguished in the perikarya, continued as massive formations even into the proximal parts of the dendrites. With decreasing neuronal size the Nissl substance became more uniformly distributed in the cytoplasm and more seldom stained as extensive bodies.

Nuclear indentations were no longer seen in the giant neurons (30–55 μ); by contrast, they were common in the medium-sized (15–35 μ) and small neurons (10–20 μ). Perinuclear cisterns were seen exclusively in the small neurons, where they sometimes seemed to communicate with the rough endoplasmic reticulum tubules. The cell organelles in the cytoplasm of the giant and medium-sized neurons did not differ to any appreciable extent from those seen in the two foregoing age groups, except that peculiar inclusion bodies occurred. These inclusions, often seen in groups

Fig. 35 — Light micrograph of the dorsocaudal part of the lateral vestibular nucleus of an adult rat. A typical group of neurons of various sizes, in which giant neurons predominate, is seen. Glial cells of both types (arrows) are seen in the strongly myelinated surrounding neuropil. Toluidine blue stained Epon section. × 400

and the perikarya of glial cells with their processes. There were numerous axo-dendritic and also axo-axonal synapses as well as sometimes synaptic complexes composed of axons and dendrites. These axo-dendritic complexes were so compact that astrocytic processes hardly never penetrated between them.

Dendritic expansions, mostly filled with slender elongated mitochondria usually disposed in parallel array and containing only a few other cell organelles were seen. In addition these expansions as a rule had abundant conglomerations of glycogen granules (Fig. 10) and sometimes distorted mitochondria which also occasionally contained glycogen granules. Usually 1—2 small axon terminals synapsed on them. Axon terminals deviating markedly in structure from the remainder were also occasionally seen. They showed the same characteristic features as have already been described earlier.

The fine structure of this giant neuron is typical, and numerous typical axon terminals of various types synapse on the neuronal cell body. × 5 320

b. — View of the same giant neuron in an almost adjacent semithin section. This light micrograph shows two inclusion bodies, of which only the larger one is seen in the electron micrograph. Toluidine blue stained Epon section. × 600

of 2–3 (Fig 37 a and b) consisted of fibrils twisted round each other and varied in diameter from 1–5 μ

In light microscopic sections stained with toluidine blue these inclusions remained unstained and were thus readily distinguished They were often centrally located in the cytoplasm of giant cells. Most inclusions were round or ovoid (Fig 38) and were separated from the surrounding cytoplasm by a membrane This was for the most part single though it seemed to be double in some sites or even of a simple tubular structure There was one variety (Fig 39) with a very thick wall, mostly made up of laminated partitions varying considerably in number in different parts of the inclusion. The content consisted of the same kind of fibrils as described above but their number seemed to decrease with increasing wall thickness.

In small neurons the rough endoplasmic reticulum tubules were more uniformly scattered over the cytoplasm than before The tubules were similar in shape in neurons of different sizes, but in the small neurons they were less numerous. Neurofilaments and microtubules also occurred in the cytoplasm of small neurons.

SYNAPSES

Axo-somatic synapses

The total number of axon terminals synapsing on the giant neuron profiles was of the same order as at the foregoing age varying from 14–27 In general the largest of the giant neurons had more synapses and the majority of them were small The number of large terminals varied from 3–5 that of slender terminals from 1–3 per giant neuron figure (Table I)

There was considerable variation in the number of terminals per cell profile synapsing on medium sized neurons. The total number varied from 11–19 but the mean was nearer the first mentioned figure The majority were small terminals, 1–3 large ones and 0–2 slender terminals per medium sized neuron profile.

Both large and medium sized neurons were quite often in synaptic contact with elongated terminals with an extensive synaptic zone.

Only a few axon terminals synapsed on the small neurons. There were usually 1–3 small terminals per cell profile.

The large axon terminals were either spherical or elongated In the former case the ending appeared to be deeply impressed into the cell body Most often these terminals were spindle shaped however with a length of up to 10–12 μ and a width never exceeding 3–4 μ They often differed from the other terminals in their dark appearance which seemed to be due to their high density of agranular synaptic vesicles. They generally also contained up to 10–50 small mitochondria Granular synaptic vesicles were rare An average of 3–5 short "active zones" occurred per terminal and they did not exceed 0.5 μ in length Desmosomal junctions were also seen in nearly all terminals but no "gap junctions" occurred

The structure of the slender axon terminal had not changed Their length often varied from 10–15 μ while their width was usually under 1 μ "Active zones" were numerous, often amounting to 10–15 per terminal Desmosomal junctions were rare Granular vesicles were seldom encountered in the slender axon terminals.

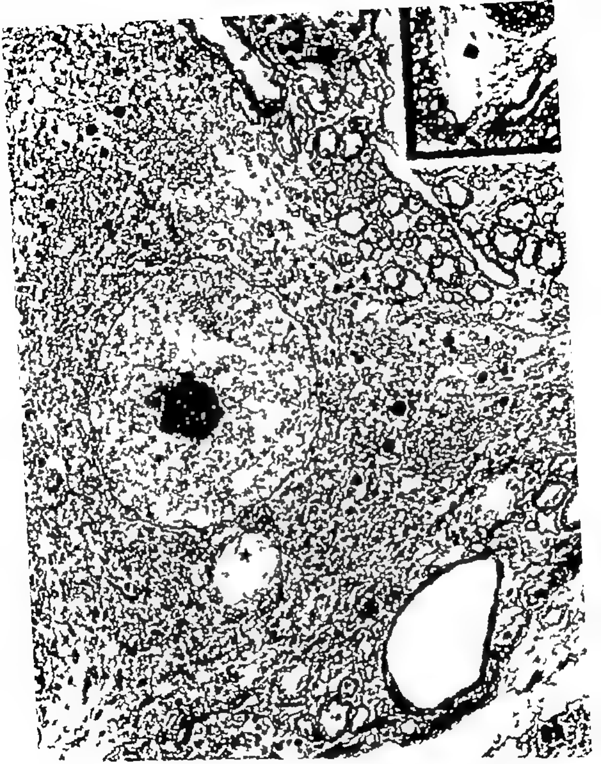

Fig. 17. — General electron micrographic view of the lateral vestibular nucleus of an adult rat showing a giant neuron with an inclusion body of fibrillar type (asterisk) centrally in the cytoplasm. Fig 38 — The same f brillary inclusion as in Figs. 3 at high n agn f cation. × 16 000.

The small axon terminals were spherical or elongated and measured from 0.5—3 μ in diameter The synapsing side was flattened and followed the cytomembrane Most often they had one long sometimes two straight junctional "active zones" Quite frequently a band of electron dense material was seen beneath the postsynaptic membrane No other junctional zones were discernible in these terminals, which contained abundant agranular synaptic vesicles. The majority of the small terminals contained some granular vesicles, though aggregations of as many a 15—20 per terminal were also occasionally seen Just as in the other terminals, the size of these large granular vesicles varied from 800—1500 Å and the diameter of their dense core from 400—700 Å Otherwise their structure, too was the same as previously described.

Axo-dendritic synapses

The distribution of various kinds of synapsing endings on the dendrites resembled that seen in the foregoing age groups Thorns were common, particularly on th proximal parts of the dendrites. They were generally smaller and narrower than on the neuronal cytomembranes.

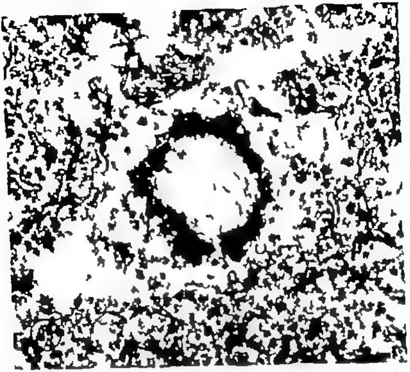

Fig. 39. — Electron micrograph showing another type of fibrillary inclusion with a multi-loculated envelope in the cytoplasm of giant neuron in the lateral vestibular nucleus of an adult rat. × 40 000

Axo-axonal synapses

Small axon terminals synapsed in great number on large terminals, which in turn were in synaptic contact with neurons or dendrites. There were sometimes 2–3 axo-axonal synapses per one presynaptic large terminal. Occasionally a large terminal synapsed not only on a neuron but also on an adjacent small axon terminal, which did not, however, seem to synapse on the neuron in question in the same plane of section. Moreover, axon terminals resembling the large and small terminals on the perikaryonal or dendritic surface of neurons synapsed in larger numbers on the axon hillocks than on the initial segments of axons originating from neurons of all sizes (Figs. 41 and 42). Lateral vestibular glomeruli were more frequently seen in the neuropil than at the foregoing age. In these axo-dendritic synaptic complexes, central axon frequently synapsed on the surrounding dendrites. A peripheral axon occasionally synapsed on central axon, but a contact in the opposite direction was never seen in adult animals.

NEUROGLIA

Glial cells were scattered all over the nucleus. Strongly myelinated areas were the site of predilection of the oligodendrocytes, which occasionally were also seen in groups round capillaries. When these cells were located close to neurons, the latter

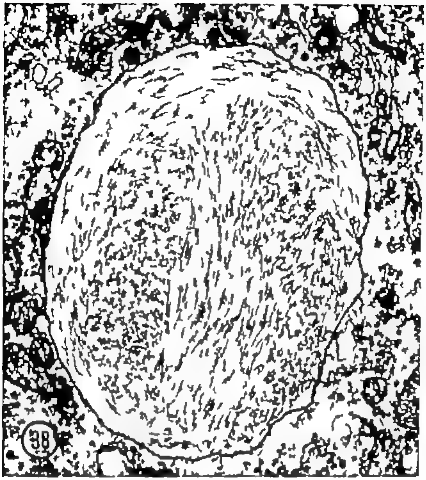

Fig. 38. — The same fibrillary inclusion as in Figs. 3 at higher magnification × 16 000.

The small axon terminals were spherical or elongated and measured from 0.5–5 μ in diameter. The synapsing side was flattened and followed the cytomembrane. Most often they had one long, sometimes two straight junctional "active zones". Quite frequently a band of electron dense material was seen beneath the postsynaptic membrane. No other junctional zones were discernible in these terminals, which contained abundant agranular synaptic vesicles. The majority of the small terminals contained some granular vesicles, though aggregations of as many as 15–20 per terminal were also occasionally seen. Just as in the other terminals, the size of these large granular vesicles varied from 800–1500 Å and the diameter of their dense core from 400–700 Å. Otherwise their structure, too, was the same as previously described.

Axo-dendritic synapses

The distribution of various kinds of synapsing endings on the dendrites resembled that seen in the foregoing age groups. Thorns were common, particularly on the proximal parts of the dendrites. They were generally smaller and narrower than on the neuronal cytomembranes.

Fig. 40 — Electron micrograph of th lateral vestibular nucleus f an adult rat showing a dendritic expansion containing numerous mitochondria and glycogen granules Th adjacent glial cells are oligodendrocytes. × 20 000

were usually medium-sized or small The number of oligodendrocytes per unit of surface area and their predominance among the total glial cell population had not changed, about 60–70 per cent of the glial cells being oligodendrocytes. In the light microscope they were easily distinguished from astrocytes by their heavy toluidine blue staining and the sharp demarcation of their cytoplasm and the special features of their nuclei. The poor staining and the variable shape of the nucleus and cell body facilitated the distinction of the astrocytes from the oligodendrocytes and also from small neurons even clearly in the light microscope

The size of the oligodendrocytic profiles varied from 6–15 μ Oligodendrocytes could be seen with the electron microscope to have an almost spherical to elongated nucleus with a sharply defined nucleolus eccentrically situated in the cytoplasm. The chromatin was very seldom uniformly distributed in the nucleoplasm it often formed numerous chromatin clumps peripherally aggregated along the nuclear envelope. The cytoplasm contained an abundance of ribosomes, a proportion of which was attached to the membranes of the rough endoplasmic reticulum. The tubules of the rough endoplasmic reticulum were usually short, though longer tubules were also seen, particularly round the nuclei. These tubules were always densely studded with ribosomes.

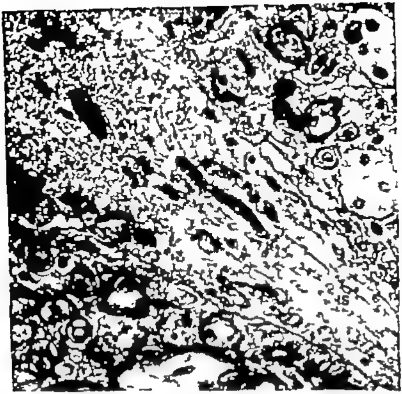

Fig 41 – Electron micrograph of the lateral vestibular nucleus of an adult rat, showing an axon sent off by a giant neuron. The axon hillock region (AH) and the most proximal part of the initial segment (IS) of the axon are seen. Bundles of fasciculated microtubules are visible in the cytoplasm, as well as granular material beneath the cytomembrane of the initial axonal segment. Synapsing axon terminals are more numerous on the axon hillock than on the neuronal surface of the initial segment. × 8 000

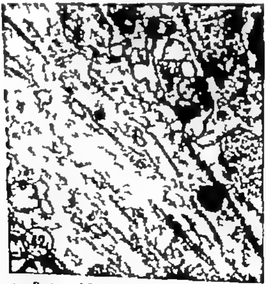

Fig 42 – Higher magnification of Fig 41. A small axon terminal is seen synapsing on the initial axonal segment, and the granular material beneath the cytomembrane of the initial segment is more clearly distinguished. × 16 000

The mitochondria were prominent, being mostly small and plump though rod-shaped mitochondria also occurred The Golgi apparatus was well developed and extensive. Moreover the cytoplasm contained vesicles of various sizes, dark multivesicular bodies and at places a dense fibrillar network. When situated near a neuron the oligodendrocytes were mostly separated from the neuronal cytomembrane by myelinated fibres or dendrites, a layer of axon terminals and slender processes of the astrocytic processes. The relationship between the oligodendrocytes and the small and medium-sized neurons often seemed to be closer than before Very often the former were only separated from the latter by thin astrocytic feet, or occasionally they even seemed to be directly apposed.

The astrocytes were satellites of neurons the giant ones in particular They stained with toluidine blue more weakly than any other cells in the lateral vestibular nucleus. The diameter of the profiles of astrocytes varied from 6—16 μ The nucleus of the astrocytes was ovoid sometimes pear shaped or spheroid. The pleomorphism typical of the earlier stages had disappeared The chromatin was usually uniformly distributed over the nucleoplasm The nucleolus was smooth and eccentrically placed. The cytoplasm appeared to be very lucent owing to the sparsity of the cytoplasmic organelles. The rough endoplasmic reticulum consisted of short tubules, usually studded with ribosomes. The free ribosomes were mostly thinly scattered in clusters. The Golgi cisterns were well developed, but not numerous. The mitochondria were small and not very numerous. The most characteristic feature of the cytoplasm was the presence of bundles of filaments, which in great number seemed to penetrate into the numerous processes Moreover the cytoplasm contained variously sized vesicles, glycogen like granules and multivesicular bodies. The numerous processes branched off in increasing numbers, everywhere penetrating between the structures of the neuropil separating them from each other and from the neurons.

When the astrocytes were situated in the vicinity of neurons, giant ones in particular their extensive processes were usually in direct contact with the neuronal cytomembranes. Mostly the astrocytic cell body was separated from the neuronal cytomembrane by a zone of axon terminals. Sometimes, however the perikarya of the two cells were in direct contact with one another

DISCUSSION

NEURONAL DEVELOPMENT

The literature contains a considerable amount of data on the morphological development of nerve cells in various parts of the central nervous system (e.g. Brizzee & Jacobs, 1959, Skoglund, 1969, Mellström & Skoglund, 1969, Conradi & Skoglund, 1969 a and b, Altman, 1972 a, b and c). Certain quantitative results on the maturation of the neurons are also available (Haltia, 1970). According to the above-mentioned and other investigations, the postnatal development of neurons varies widely in different parts of the central nervous system, reaching maturity at different times. Furthermore, wide variations in neuronal development have been observed even within the same parts of the central nervous system, for example between the various segments of the spinal cord (Mellström & Skoglund, 1969) and the various parts of the neocortex (Schwartz et al. 1968). Furthermore, the results obtained by different authors in the same areas may not be consistent, owing in part to the use of different methods. For this reason, comparison of results is difficult, as has also been pointed out previously (e.g. Mellström & Skoglund, 1969, Haltia, 1970).

Ultrastructurally the small neurons in the lateral vestibular nucleus of the adult rat resembled the neurons of the second category in the lateral cervical nucleus of the adult cat (Westman, 1971). In both, the cell nucleus is relatively large, the endoplasmic reticulum is poorly developed, the mitochondria are few in number, somatic thorns are lacking, and the axon terminal covering on the cell body is sparse. Moreover the nerve endings contacting the small neurons form a relatively homogeneous population. Neurons of small size with similar properties have also been described in the *fascia dentata* (Blackstad & Dahl, 1962) and in the lateral geniculate body (Karlsson, 1966) of the adult rat. Although the small neurons in different parts of the central nervous system have been quite extensively investigated in recent years (e.g. LaVelle & LaVelle, 1970, Altman, 1970, 1972 b and c), the information concerning their development on the ultrastructural level is relatively meagre.

Considering that the giant neurons of Deiters nucleus structurally resemble the motoneurons of the spinal cord and that numerous investigations, both morphological and quantitative, have been performed on the latter, a comparison of the development of the motoneurons and giant cells seems to be of interest.

It was shown in the present study that the giant cells of the lateral vestibular nucleus steadily increased in size *throughout the first* postnatal month, though most rapidly during the first 10 days. At the same time the dendritic tree became steadily

The mitochondria were prominent being mostly small and plump, though rod-shaped mitochondria also occurred. The Golgi apparatus was well developed and extensive Moreover the cytoplasm contained vesicles of various sizes, dark multivesicular bodies and at places a dense fibrillar network When situated near a neuron the oligodendrocytes were mostly separated from the neuronal cytomembrane by myelinated fibres or dendrites, a layer of axon terminals and slender processes of the astrocytic processes. The relationship between the oligodendrocytes and the small and medium-sized neurons often seemed to be closer than before. Very often the former were only separated from the latter by thin astrocytic feet or occasionally they even seemed to be directly apposed

The astrocytes were satellites of neurons, the giant ones in particular They stained with toluidine blue more weakly than any other cells in the lateral vestibular nucleus. The diameter of the profiles of astrocytes varied from 6–16 μ The nucleus of the astrocytes was ovoid sometimes pear-shaped or spheroid The pleomorphism typical of the earlier stages had disappeared The chromatin was usually uniformly distributed over the nucleoplasm The nucleolus was smooth and eccentrically placed The cytoplasm appeared to be very lucent owing to the sparsity of the cytoplasmic organelles. The rough endoplasmic reticulum consisted of short tubules, usually studded with ribosomes. The free ribosomes were mostly thinly scattered in clusters. The Golgi cisterns were well developed but not numerous The mitochondria were small and not very numerous. The most characteristic feature of the cytoplasm was the presence of bundles of filaments, which in great number seemed to penetrate into the numerous processes. Moreover the cytoplasm contained variously sized vesicles, glycogen like granules and multivesicular bodies The numerous processes branched off in increasing numbers, everywhere penetrating between the structures of the neuropil separating them from each other and from the neurons.

When the astrocytes were situated in the vicinity of neurons, giant ones in particular their extensive processes were usually in direct contact with the neuronal cytomembranes Mostly the astrocytic cell body was separated from the neuronal cytomembrane by a zone of axon terminals. Sometimes, however the perikarya of the two cells were in direct contact with one another

prenatally (Czerwicki, 1969). Concerning the development of the cytoplasmic organelles in the nerve cell cytoplasm, these observations are in agreement with previous studies even on sympathetic nerve cells (Eranko, 1972 a and b) which in adult rats are rather different from the cells of the Deiters nucleus.

In the present study the most obvious differences were observed between the fine structural development of the giant and small neurons. The changes in the structure of the small neurons were slight, the rate of change was also slow and the onset of changes was definitely later than in the giant and medium-sized neurons. Previous investigators have also reported that small cells poor in Nissl substance develop very slowly after passing the initial growth period (LaVelle 1956; Mellström & Skoglund, 1969 Altman, 1970). In the present material the small neurons attained their final nuclear and somal size during the first postnatal week, but the poorly developed rough endoplasmic reticulum and the ribosomes did not assume an appearance resembling the adult stage until the end of the first postnatal month, when they were becoming organized into small Nissl bodies. Communications between the nuclear envelope and the cisterns of rough endoplasmic reticulum, such as occurred in abundance immediately after birth also in the medium-sized neurons, were preserved in great number in the small neurons throughout the development in the cat (Mugnaini et al., 1967 b) Flattened sacs of the rough endoplasmic reticulum and subsurface cisterns previously described (Gray 1961 Rosenbluth, 1962 Mugnaini et al 1967 b Sotelo & Palay 1968) were considerably more numerous in the small neurons than in the large ones throughout the development. The role of the large number of subsurface cisterns in the small neurons, their communications between the perinuclear cisterns of the nuclear envelope, is not fully understood. It has been suggested that this system of channels may be concerned with the movements of ions or of metabolites (Rosenbluth, 1962) It has been shown that nuclear indentations and nucleotides associated with the nuclear membranes are related to the formation of cytoplasmic proteins (Hydén, 1943) In the lateral vestibular nucleus the number of nuclear indentations slowly increased in the small neurons in parallel with the development of the rough endoplasmic reticulum during the first postnatal month. The same phenomenon was also observed in the giant and medium-sized neurons during the earlier development. This is presumably a sign of intense synthetic activity in the small neurons even at the adult stage and it has been suggested that the preservation of the channel-like system and nuclear indentation in the small neurons even at the adult stage may be the morphological equivalent of this activity (Mugnaini et al 1967 b)

Since the regulation of the protein synthesis in developing mammalian nerve cells is poorly understood (Mandel & Jacob, 1970) various explanations of the rapid accumulation of the Nissl substance have been offered. Considering that cytoplasmic RNA constitutes an essential part of the protein synthetizing apparatus of the cell (de Man & Noorduyn, 1969) its marked increase postnatally obviously augments the neuronal protein synthesis (e.g. Eschner & Glees, 1963 Wechsler, 1966) It has also been assumed that the increase in the number of mitochondria as such observed in some investigations (Flexner, 1955 Richter 1967 Seiler, 1969) or in combination with enhanced energy metabolism (Seiler, 1969) is connected with accelerated RNA and protein synthesis and may also explain the observed pronounced increase in the number of mitochondria in Deiters nucleus during the early postnatal period.

more extensive, and multipolar and elongated cells increased in number. Since the nucleus did not increase in size after birth, an extension of the perikaryon and its processes was involved. Similar observations have been made on the growth of motoneurons during the first postnatal month (Ngowyang 1930, Ford & Cohan, 1968). The results in question were confirmed by Mellström & Skoglund (1969) who found however that both the nucleus and cell body of the motoneurons increased in size almost exclusively during the second fortnight of postnatal life. It thus appears that in the giant cells and particularly in the medium sized neurons of the lateral vestibular nucleus, the growth period of both the nucleus and perikaryon occurred considerably earlier than in the motoneurons of the anterior horn of the spinal cord.

The population of giant neurons of the lateral vestibular nucleus appeared to follow a relatively uniform pattern of development. The changes in the nucleus were slight, similar features being observed in the nuclei of the giant neurons of both newborn rats and adult animals. The nuclear indentations did, however, clearly increase in size and number until the seventh postnatal day. At this stage they sometimes also contained rough endoplasmic reticulum tubules, besides ribosomes, and often extended to the vicinity of the nucleolus. Subsequently the nuclear indentations gradually decreased in size and number so that none were observed in the giant neurons of the adult rat, but were still frequent findings in the medium-sized and small neurons. The rough endoplasmic reticulum and free ribosomes in the giant neurons also increased most during the first postnatal week. This was in agreement with earlier hypotheses on the association between nuclear indentitations and the formation of cytoplasmic proteins (Hydén, 1946).

An interesting change took place in the cisterns of the rough endoplasmic reticulum, which was scanty and poorly organized in the newborn. Its maturation into highly organized groups of tubules disposed in parallel array and clustering of ribosomes mainly occurred before the fourth postnatal day. The organization and the quantitative increase of both the rough endoplasmic reticulum and free ribosomes were most intensive from the fourth to the seventh day continuing more slowly to the tenth postnatal day. The well-developed Golgi membranes increased in number during the same period. The number of neurofilaments increased most during the first two postnatal weeks, which was later than the maturation of the endoplasmic reticulum.

The fine structural observations of the present study complement those reported in a quantitative cytochemical investigation on neuronal development in the anterior spinal horn in the rat (Haltia, 1970). In this, relatively slight changes were observed in the dry mass and mean neuronal RNA content of the neurons during the first three to five days of postnatal life followed by an abrupt rise in the RNA content to the eighth day and an increase in neuronal dry mass thereafter. The ratio of RNA/dry mass also appeared to rise for the first eight days of life and then remained at approximately the same level until adult age. Haltia (1970) pointed out that an intense accumulation of RNA and protein occurred mainly postnatally in the neurons in contrast to other somatic cells.

Similar results have been reported in a study on the development of the mesencephalic trigeminal neurons in the rat, in which the increase in RNA was found to be much greater and more rapid between the second and ninth postnatal days than

prenatally (Grewzyk, 1969). Concerning the development of the cytoplasmic organelles in the nerve cell cytoplasm, these observations are in agreement with previous studies even on sympathetic nerve cells (Eränkö, 1972 a and b), which in adult rats are rather different from the cells of the Deiters nucleus.

In the present study the most obvious differences were observed between the fine structural development of the giant and small neurons. The changes in the structure of the small neurons were slight, the rate of change was also slow and the onset of changes was definitely later than in the giant and medium-sized neurons. Previous investigators have also reported that small cells poor in Nissl substance develop very slowly after passing the initial growth period (LaVelle, 1956; Mellström & Skoglund, 1969; Altman, 1970). In the present material the small neurons attained their final nuclear and somal size during the first postnatal week, but the poorly developed rough endoplasmic reticulum and the ribosomes did not assume an appearance resembling the adult stage until the end of the first postnatal month, when they were becoming organized into small Nissl bodies. Communications between the nuclear envelope and the cisterns of rough endoplasmic reticulum, such as occurred in abundance immediately after birth also in the medium-sized neurons, were preserved in great number in the small neurons throughout the development in the cat (Mugnaini et al., 1967 b). Flattened sacs of the rough endoplasmic reticulum and subsurface cisterns previously described (Gray, 1961; Rosenbluth, 1962; Mugnaini et al., 1967 b; Sotelo & Palay 1968) were considerably more numerous in the small neurons than in the large ones throughout the development. The role of the large number of subsurface cisterns in the small neurons, their communications between the perinuclear cisterns of the nuclear envelope, is not fully understood. It has been suggested that this system of channels may be concerned with the movements of ions or of metabolites (Rosenbluth, 1962). It has been shown that nuclear indentations and nucleotides associated with the nuclear membranes are related to the formation of cytoplasmic proteins (Hydén, 1943). In the lateral vestibular nucleus the number of nuclear indentations slowly increased in the small neurons in parallel with the development of the rough endoplasmic reticulum during the first postnatal month. The same phenomenon was also observed in the giant and medium-sized neurons during the earlier development. This is presumably a sign of intense synthetic activity in the small neurons even at the adult stage and it has been suggested that the preservation of the channel-like system and nuclear indentation in the small neurons even at the adult stage may be the morphological equivalent of this activity (Mugnaini et al., 1967 b).

Since the regulation of the protein synthesis in developing mammalian nerve cells is poorly understood (Mandel & Jacob, 1970), various explanations of the rapid accumulation of the Nissl substance have been offered. Considering that cytoplasmic RNA constitutes an essential part of the protein synthetizing apparatus of the cell (de Man & Noorduyn, 1969), its marked increase postnatally obviously augments the neuronal protein synthesis (e.g. Eschner & Olsen, 1963; Wechsler, 1966). It has also been assumed that the increase in the number of mitochondria as such observed in some investigations (Flexner, 1955; Richter, 1967; Seller, 1969) or in combination with enhanced energy metabolism (Seller, 1969) is connected with accelerated RNA and protein synthesis and may also explain the observed pronounced increase in the number of mitochondria in Deiters' nucleus during the early postnatal period.

more extensive, and multipolar and elongated cells increased in number Since the nucleus did not increase in size after birth, an extension of the perikaryon and its processes was involved. Similar observations have been made on the growth of motoneurons during the first postnatal month (Ngowyang 1930 Ford & Cohan, 1968) The results in question were confirmed by Mellström & Skoglund (1969) who found, however that both the nucleus and cell body of the motoneurons increased in size almost exclusively during the second fortnight of postnatal life. It thus appears that in the giant cells and particularly in the medium sized neurons of the lateral vestibular nucleus, the growth period of both the nucleus and perikaryon occurred considerably earlier than in the motoneurons of the anterior horn of the spinal cord.

The population of giant neurons of the lateral vestibular nucleus appeared to follow a relatively uniform pattern of development. The changes in the nucleus were slight, similar features being observed in the nuclei of the giant neurons of both new born rats and adult animals. The nuclear indentations did, however clearly increase in size and number until the seventh postnatal day At this stage they sometimes also contained rough endoplasmic reticulum tubules, besides ribosomes, and often extended to the vicinity of the nucleolus. Subsequently the nuclear indentations gradually decreased in size and number so that none were observed in the giant neurons of the adult rat, but were still frequent findings in the medium-sized and small neurons. The rough endoplasmic reticulum and free ribosomes in the giant neurons also increased most during the first postnatal week. This was in agreement with earlier hypotheses on the association between nuclear indentations and the formation of cytoplasmic proteins (Hydén, 1943)

An interesting change took place in the cisterns of the rough endoplasmic reticulum, which was scanty and poorly organized in the newborn. Its maturation into highly organized groups of tubules disposed in parallel array and clustering of ribosomes mainly occurred before the fourth postnatal day The organization and the quantitative increase of both the rough endoplasmic reticulum and free ribosomes were most intensive from the fourth to the seventh day continuing more slowly to the tenth postnatal day The well-developed Golgi membranes increased in number during the same period. The number of neurofilaments increased most during the first two postnatal weeks, which was later than the maturation of the endoplasmic reticulum.

The fine structural observations of the present study complement those reported in a quantitative cytochemical investigation on neuronal development in the anterior spinal horn in the rat (Haltia, 1970) In this, relatively slight changes were observed in the dry mass and mean neuronal RNA content of the neurons during the first three to five days of postnatal life followed by an abrupt rise in the RNA content to the eighth day and an increase in neuronal dry mass thereafter The ratio of RNA/dry mass also appeared to rise for the first eight days of life and then remained at approximately the same level until adult age Haltia (1970) pointed out that an intense accumulation of RNA and protein occurred mainly postnatally in the neurons in contrast to other somatic cells.

Similar results have been reported in a study on the development of the mesencephalic trigeminal neurons in the rat, in which the increase in RNA was found to be much greater and more rapid between the second and ninth postnatal days than

other cytoplasmic organelles. They were covered by only a few synapsing axon terminal. Similar structures have been described in the cerebellar cortex and hypothalamus (Chandler & Willis, 1966) in autonomic ganglia (Sulkin et al., 1968) and in the cerebral cortex (Dahl, 1965). On the other hand it has been reported that the first synapses of vagal fibres appearing after deafferentation in the superior cervical ganglion were located on growing tips of dendrites (Ceccarelli, 1968). In this study similar synapses were not observed until the end of the first postnatal month, when the neuronal elements including the dendrites had passed their most intense stage of development. These expansions were always located on the distal parts of the dendrites, which was in agreement with previous findings (Mugnaini et al. 1967 b) Sotelo & Palay 1968). The question of whether they were dilations or actual terminations of dendrites cannot be answered without investigating serial sections. Their complete absence in the early stages of development of the lateral vestibular nucleus favours the view that they were growing or expanding tips of changing dendrites in growing or regenerating mature nerve cell (Sotelo & Palay 1968, 1971)

In recent investigations enlarged axon terminals containing a variety of unusual structures have been observed in the central nervous system of different animals. In general they have been considered to be due to some kind of chronic degenerative process possibly caused by nutritional deficiency or some noxious agent (see references Sotelo & Palay 1971) Hashimoto & Palay (1965) were the first to draw attention to the fact that nerve endings with similar inclusions are seen in the nucleus gracilis of normal adult rats and cats. These authors suggested that the altered axon terminals are the result of a physiological degenerative process, starting in early life and continuing into maturity. Similar peculiar nerve endings have since been described in the normal cerebellum of various animal species (Andres, 1965; Morales & Duncan, 1966; Raine & Field 1967; Hámori & Szentágothai, 1968; Hirano et al. 1968, 1969; Sotelo, 1969) and in the lateral vestibular nucleus of the adult cat (Mugnaini et al. 1967 b) and the adult rat (Sotelo & Palay 1971).

Similar enlarged, altered axon terminals were observed in this study though only in the mature or nearly mature lateral vestibular nucleus. This finding favours the view that these endings represent the degenerative phase of a cycle of degeneration and regeneration of axon terminal in normal adults, and indicate that axonal remodelling is a process generally occurring in the mature nervous system (Sotelo & Palay 1971). Degeneration of axon terminals ought to be followed by the generation of new endings if continuous axonal remodelling takes place in the central nervous system. So far no evidence of regenerating axon terminals has been reported. The results obtained in this present study do not support the assumption of Hashimoto & Palay (1965) that axonal degeneration starts early in life.

DEVELOPMENT OF SYNAPTIC CONNECTIONS

The synaptogenesis of various parts of the central nervous system has in recent years mainly been studied in the cerebral cortex (Voeller et al. 1963; Pappas & Purpura, 1964; Meller et al. 1968; Adinolfi, 1971 a and b) but also in the hippocampus (Blackstad & Kjaerheim, 1961; Blackstad & Flood, 1963; Purpura & Pappas, 1968

STRUCTURES OF THE NEUROPIL

Most of the neuropil of the lateral vestibular nucleus of the newborn rat was found to be occupied by dendritic or axonal profiles of various sizes. Axonal elements predominated, because the dendritic tree of all neurons, though especially that of the small and medium sized neurons was still poorly developed as in other parts of the central nervous system (e.g. Adinolfi, 1972 Altman 1972 b) The axonal profiles were also of small calibre in the more distant neuropil, where myelinated axons of large calibre were abundant in the adult rats. Identifying axons and dendrites was often difficult during the early neonatal period, because all the axons were still unmyelinated and differences in the fine structure did not necessarily occur as previously encountered in other parts of the central nervous system (Schwartz et al., 1968) Larger axons and dendrites were more readily distinguished, because the larger dendrites often contained rough endoplasmic reticulum, mitochondria and occasional multivesicular bodies. Both axons and dendrites rapidly increased in calibre and the adult size was often attained by the end of the first postnatal week, and then it was possible to distinguish most of the axons from the dendrites.

The oligodendrocytes rapidly increased in number and myelination started round the large axons of the vestibular nerve. By the end of the first postnatal week the largest axons with early myelination figures were scattered all over the area of the lateral vestibular nucleus. These are probably fibres by passage through the lateral vestibular nucleus to the other vestibular nuclei or the cerebellum. The most intensive phase of myelination took place during the second and third postnatal weeks By the tenth postnatal day large areas of the neuropil were mainly occupied by myelinated axons of large and medium calibre, while all the axons of small calibre were unmyelinated. By the end of the third postnatal week most of the small axons, even in the close vicinity of neurons, were myelinated Myelinated axons also synapsed on the cell bodies of giant neurons, resembling the picture seen in adult animals. In agreement with previous observations (Sotelo & Palay 1968) immature myelin figures were seen round small axons even in the adults.

The development of the dendrites of all neurons was largely similar No major differences in fine structure were observed between the dendrites of the giant cells and the dendrites of the smaller cells. The dendritic tree of the giant neurons was remarkable from birth, while dendrites sent off by small neurons were not very often encountered even in sections representing the older age groups investigated. The cytoplasmic content of the small dendrites was poorer during the early postnatal period than at later stages. By contrast at the end of the first postnatal week the proximal parts of the largest dendrites of giant neurons contained tubules of rough endoplasmic reticulum and rosettes of ribosomes forming groups resembling the Nissl bodies of the adult stage Microtubules and neurofilaments were also numerous, and clusters of free ribosomes were observed even in the smallest dendritic branches. The diameter of the proximal parts of the largest dendrites doubled during the course of the postnatal development as in the motoneurons of the spinal cord (Conradi & Skoglund 1969 a)

Dendrites showing certain characteristic deviating features were encountered at later stages of development These may be described as dendritic expansions, filled with a large number of mitochondria and glycogen granules, but only few of the

other cytoplasmic organelles. They were covered by only few synapsing axon terminals. Similar structures have been described in th cerebellar cortex and hypothalamus (Chandler & Willis, 1966) in autonomic ganglia (Sulkin et al 1968) and in the cerebral cortex (Dahl, 1963). On the other hand it has been reported that the first synapses of agal f bres ppearing after deafferentation in the superior cervical ganglion were located on growing tips of dendrites (Ceccarelli, 1968). In this study similar synapses were not observed until the end of the f rst postnatal month, when the neuronal lements including the dendrites h d passed their most intense stage f development. These expansions were alw ys located on the dist l parts of the dendrites, which was in agreement with previous findings (Mugnaini et al 1967 b) Sotelo & Palay 1968). The question of whether they were dilations or actual terminations of dendrites cannot be answered without investigating serial sections. Their complete bsence in the early stages f development of the lateral vestibular nucleus f ours the iew that they were growing or expanding tips of changing dendrites in growing or regenerating matur nerv cell (Sotelo & Palay 1968, 1971).

I recent in estigations enlarged xon terminals containing a variety of unusual structures h ve been bserved in the central nervous system f different animals. In general they hav been considered to be due to some kind f chronic degenerative process possibly caused by nutritional deficiency or som noxious gent (see references Sotelo & Palay 1971). H shimoto & Palay (1965) were the first to draw ttention to the fact that nerv endings with similar inclusions are seen in the nucleus gracilis of normal adult rats and cats. These authors suggested that the altered axon terminals are the result f phy siological degenerative process, starting in earl life nd continuing into maturity. Simil peculia nerv endings have since been described in the normal cerebellum of arious animal species (Andres, 1965. Morales & Duncan 1966 Rayne & Field, 1967. Hámori & Szentágothai, 1968 Hirano et l 1968, 1967 Sotelo 1969) nd in the lateral vestibular nucleus f the adult cat (Mugnaini et l 1967 b) and the dult rat (Sotelo & P lay 1971).

Simila enlarged, altered axon terminals were observed in this study though only the mature or nea ly mature lateral estibul r nucleu. This finding f vours the iew that these endings represent the degenerative phase f a cycle of degeneration and regeneration of axon terminals in normal adults, and indicate that axonal remodelling is process generally occurring in the mature nervous system (Sotelo & Palay 1971). Degeneration of axon termin ls ought to be followed by the generation of new endings if continuous axon l remodelling takes place in the central nervous system. So far no evidence of regenerating axon terminals has been reported. The results obta ned in the present study do not support the assumption of Hashimoto & Palay (1965) that axonal degeneration starts early in life.

DEVELOPMENT OF SYNAPTIC CONNECTIONS

The synaptogenesis f rious parts f the central nervous system has in recent years mainly been studied the cerebral cortex (Voeller et al 1963. Pappas & Purpura, 1964 Meller et l 1968 Adinolfi, 1971 and b) but also in the hippocampus (Blackstad & Kjaerheim, 1961 Blackstad & Flood, 1963 Purpura & Pappas, 1968

STRUCTURES OF THE NEUROPIL

Most of the neuropil of the lateral vestibular nucleus of the newborn rat was found to be occupied by dendritic or axonal profiles of various sizes. Axonal elements predominated because the dendritic tree of all neurons, though especially that of the small and medium sized neurons, was still poorly developed as in other parts of the central nervous system (e.g. Adinolfi, 1972 Altman, 1972 b) The axonal profiles were also of small calibre in the more distant neuropil, where myelinated axons of large calibre were abundant in the adult rats. Identifying axons and dendrites was often difficult during the early neonatal period, because all the axons were still unmyelinated and differences in the fine structure did not necessarily occur as previously encountered in other parts of the central nervous system (Schwartz et al. 1968) Larger axons and dendrites were more readily distinguished, because the larger dendrites often contained rough endoplasmic reticulum mitochondria and occasional multivesicular bodies. Both axons and dendrites rapidly increased in calibre and the adult size was often attained by the end of the first postnatal week, and then it was possible to distinguish most of the axons from the dendrites.

The oligodendrocytes rapidly increased in number and myelination started round the large axons of the vestibular nerve By the end of the first postnatal week the largest axons with early myelination figures were scattered all over the area of the lateral vestibular nucleus. These are probably fibres by passage through the lateral vestibular nucleus to the other vestibular nuclei or the cerebellum. The most intensive phase of myelination took place during the second and third postnatal weeks. By the tenth postnatal day large areas of the neuropil were mainly occupied by myelinated axons of large and medium calibre, while all the axons of small calibre were unmyelinated. By the end of the third postnatal week most of the small axons, even in the close vicinity of neurons, were myelinated. Myelinated axons also synapsed on the cell bodies of giant neurons, resembling the picture seen in adult animals. In agreement with previous observations (Sotelo & Palay 1968) immature myelin figures were seen round small axons even in the adults.

The development of the dendrites of all neurons was largely similar No major differences in fine structure were observed between the dendrites of the giant cells and the dendrites of the smaller cells. The dendritic tree of the giant neurons was remarkable from birth while dendrites sent off by small neurons were not very often encountered even in sections representing the older age groups investigated The cytoplasmic content of the small dendrites was poorer during the early postnatal period than at later stages. By contrast, at the end of the first postnatal week the proximal parts of the largest dendrites of giant neurons contained tubules of rough endoplasmic reticulum and rosettes of ribosomes forming groups resembling the Nissl bodies of the adult stage Microtubules and neurofilaments were also numerous, and clusters of free ribosomes were observed even in the smallest dendritic branches. The diameter of the proximal parts of the largest dendrites doubled during the course of the postnatal development as in the motoneurons of the spinal cord (Conrad & Skoglund 1969 a)

Dendrites showing certain characteristic deviating features were encountered at later stages of development These may be described as dendritic expansions, filled with a large number of mitochondria and glycogen granules, but only few of the

development, earlier in the giant neurons than in the medium-sized ones. The large axon terminals seemed to be the first to synapse on the giant and medium-sized neurons, and their number per cross-section f both giant and medium-sized neuron remained the same until the adult stage By contrast, small terminals very seldom synapsed on the perikarya of larger neurons at the newborn stage; and in contrast to other endings, the two types of slender terminals synapsed on the cell bodies of giant and medium-sized neurons only at the end of the first postnatal week. The increase in the total number of synapsing axon terminals during the first postnatal week, which continued t a slower rate until the tenth postnatal day in the medium-sized neurons, in particular was mainly due to a doubling many times over of synapsing small terminals in short time To some extent it was also due to a moderate increase in both types f synapsing slender terminals in both groups f neurons The total number of synapsing xon terminals per cross-section of both giant and medium-sized neurons was found to be t its m ximum on the tenth postnatal day Subsequently the total number f synapsing nerve endings remained the same or was somewhat lower

A reduction in the number f axo-somatic synapses has lso been observed in other parts f the central nervous system In studies f the cerebellum a loss f contact between terminals and the somal surfaces f neurons during th postnatal development has been reported (Mugnaini & Forstronen, 1967 Korngath et al., 1968), and the number of certain terminal on the cell bodies f developing spinal motoneurons decreased postnatally (Conradi & Skoglund, 1969) If the number of synapsing terminals per neuron figure really decreases in the lateral vestibula nucleus, the small endings are most l kely involved As an explanation of the loss of axon terminals t has been suggested that endings formi g double synapses leave the cell bodies and remain in contact with the neighbouring dendrites (Conradi & Skog lund 1969 a) This cannot be true for the dev loping lateral vestibular nucleus, however since small axon terminals do not form double synapses According to another theory astrocyte-like glial cells are somehow capable of removing synapsing terminals in the same way as has been found to occur on the cell bodies of regenerat ing motoneurons (Blinzinger & Kreutzberg, 1968) This explanation could also be abd for the loss of synaptic terminals possibly occurring in the giant and medium-sized neurons in Deiters nucleus, since the most intensive growth period of the astrocytic processes was bserved between the tenth and twentieth postnatal days. A regards the lateral vestibular nucleus, the most likely explanation does, however seem to be the degeneration of axon terminals observed in the present study during the later postn tal dev lopment. On the other hand, in the later age groups studied the differences in the total number of synapsing endings were too small to permit any far-reaching conclusions Moreover the material wa not very extensive, and th selection f cells f study may have distorted the results, because the number of synapsing terminals per neuron f gures ried widely in neurons of the same size and in the same age group.

Axo-dendritic synapses

In the newborn animal the total nerv ending covering was highest on the proximal parts of the dendrites in all neurons in Deiters nucleus, and until the adult stage it

Schwartz et al 1968) in the cerebellar cortex (Konishi 1966 Larramendi & Victor 1966 Mugnaini & Forströnen 1967 Larramendi, 1967) in the spinal cord (Bodian 1966 Bunge et al 1967 Conradi & Skoglund 1969 a and b) and in the lateral geniculate nucleus (Karlsson 1967) These studies have shown that synaptic connections develop at different times in different parts of the central nervous system although this development generally occurs during the first few postnatal weeks in mammals. The axo-somatic synapses on the cell bodies of motoneurons in the spinal cord are well developed at birth (Conradi & Skoglund 1969 a) and synapse formation in vestibular labyrinth has recently demonstrated to occur before the birth (Heywood et al 1975) while the corresponding structures in the cerebral cortex have not even started to develop of the birth (Voeller et al. 1963 Adinolfi 1971 b) The development of synaptic connections in the lateral vestibular nucleus of the rat as seen in the present material resembled most that of the lateral geniculate nucleus of the rat, whose fully developed neuronal connections were also seen during the first postnatal fortnight, before the animals had opened their eyelids (Karlsson 1967)

The formation of the first synaptic complexes has been accompanied by changes in the electrical activity of the tissue (Voeller et al 1963 Purpura et al., 1965 Bunge et al 1967 Schwartz et al 1968) There are no discrepancies compared to the electrophysiological observations. For example, spontaneous electrical activity steadily became more regular in the cerebral cortex during the first ten postnatal days (Crain 1952) and typical cerebellar activity was recorded on the twelfth postnatal day (Jacobs & Snider 1919) No electrophysiological data on maturation of the vestibular system are available

Axo-somatic synapses

In the present material the nerve ending covering of neurons of various sizes showed differences even in the early postnatal period The giant neurons had the most abundant nerve ending covering and the proportion of somal surfaces covered by terminals decreased with decreasing neuronal size as has previously been observed in the lateral vestibular nucleus of the adult rat (Sotelo & Palay 1970) in the lateral cervical nucleus of the adult cat (Westman 1971) in the developing motoneurons of the spinal cord (Conradi & Skoglund 1969 a) and in a three-dimensional study of two small cells in the lateral geniculate body of the adult rat (Karlsson 1966) In the present material the populations of various nerve endings on the giant and medium-sized neurons did not change during development but slender terminals first appeared at the end of the first postnatal week on the cell bodies of giant and medium sized neuron

Interneuronal connections were scanty at the time of birth in neurons of all sizes in the lateral vestibular nucleus, although all the neuronal surfaces were tightly packed with endings. The small neuron differed markedly from the larger ones, also with regard to the development of synaptic connection In newborn animal the small neurons were covered by a homogeneous population of synapsing endings, consisting only of small axon terminals These increased in number during the first few postnatal days and were still sparse at the adult stage as previously reported in the lateral vestibular nucleus of the adult rat (Sotelo & Palay 1970)

In the larger neurons, synaptic connections were regularly formed throughout the

development, earlier in th giant neurons than in the medium-sized ones. The large axon terminals seemed to be the first to synapse on the giant and medium-sized neurons, and their number per cross-section f both giant and medium-sized neuron remained the same until the ad lt stage. By contrast, small terminals very seldom synapsed on the perikary of l rger neurons t the newborn stage, and in contrast to other endings, the two types of slender terminals synapsed on the cell bodies of giant and medium-sized neurons only at the end of the first postnatal week. The increase in the total number of synapsing xon terminals during the first postnatal week, which continued at slower rate until the tenth postnatal day in the medium sized neurons, in particular was mainly due to a doubling many times over f synapsing small terminals in a short time T some extent it was also due to a moderate increase in both types f synapsing slender terminals in both groups of neurons. The total number f synapsing axon terminals per cross-section of both giant and medium-sized neurons was found to be t its maximum on the tenth postnatal day Subsequently the tot l number f syn psing nerv endings remained the same or was somewhat lower.

A reduction in the number of axo-somatic synapses has lso been observed in other parts f the central nervous system. In studies f the cerebellum a loss of contact between terminals and the somal surfaces f neurons during the postnatal development has been reported (Mugnaini & Forströnen, 1967 Kornguth et al., 1968) and the number of certai terminals on the cell bodies of developing spinal motoneurons decreased postnatally (Conrad & Skoglund, 1969 a) If the number of synapsing terminals per neuron figure really decreases i the lateral vestibular nucleus, the small endings are most likely involved As an explanation of the loss of axon terminals it has been suggested that endings forming double synapses leave the cell bodies and remain in contact with the neighbouring dendrites (Conradi & Skoglund, 1969) This cannot be true for the developing l teral vestibular nucleus, however since small on termin ls do not form double synapses. According to another theory astrocyte-like glial cells re somehow capable of removing synapsing terminals in the same way as has been found to occur on the cell bodies of regenerating motoneurons (Blinzinger & Kreutzberg, 1968) This explanation could lso be valid for the loss f synaptic terminals possibly occurring in the giant and medium sized neurons in Deiters nucleus, since the most intensive growth period of the astrocytic processes was observed between the tenth and twentieth postnatal days. As regards the lateral estibular nucleus, the most likely explanation does, however seem to be the degeneration of axon terminals observed in the present study during the later postnatal development On the other hand, in the later age groups studied the differences in the total number of synapsing endings were too small to permit any far-reaching conclusions Moreover the material wa not very extensive, and the selection of cells for st dy may have distorted the results, because the number of synapsing terminals per neuron figures varied widely in neurons of the same size and in the same age group.

Axo-dendritic synapses

I the newborn animals the total nerv ending covering was highest on the proximal parts f the dendrites in all neurons in Deiters ucleus, and until the adult stage it

Schwartz et al 1968) in the cerebellar cortex (Konl hi, 1966 Larramendi & Victor 1966 Mugnaini & Forströnen 1967 Larramendi, 1967) in the spinal cord (Bodian, 1966 Bunge et al 1967 Conradi & Skoglund 1969 a and b) and in the lateral geniculate nucleus (Karlsson, 1967) These studies have shown that synaptic connections develop at different times in different parts of the central nervous system, although this development generally occurs during the first few postnatal weeks in mammals. The axo-somatic synapses on the cell bodies of motoneurons in the spinal cord are well developed at birth (Conradi & Skoglund 1969 a) and synapse formation in vestibular labyrinth has recently demonstrated to occur before the birth (Heywood et al. 1973) while the corresponding structures in the cerebral cortex have not even started to develop of the birth (Voeller et al 1963 Adinolfi, 1971 b) The development of synaptic connections in the lateral vestibular nucleus of the rat as seen in the present material resembled most that of the lateral geniculate nucleus of the rat, whose fully developed neuronal connections were also seen during the first postnatal fortnight, before the animals had opened their eyelids (Karlsson 1967)

The formation of the first synaptic complexes has been accompanied by changes in the electrical activity of the tissue (Voeller et al., 1963 Purpura et al., 1965 Bunge et al 1967 Schwartz et al 1968) There are no discrepancies compared to the electrophysiological observations. For example, spontaneous electrical activity steadily became more regular in the cerebral cortex during the first ten postnatal days (Crain, 1952) and typical cerebellar activity was recorded on the twelfth postnatal day (Jacobs & Snider 1949) No electrophysiological data on maturation of the vestibular system are available

Axo-somatic synapses

In the present material the nerve ending covering of neurons of various sizes showed differences even in the early postnatal period The giant neurons had the most abundant nerve ending covering and the proportion of somal surfaces covered by terminals decreased with decreasing neuronal size as has previously been observed in the lateral vestibular nucleus of the adult rat (Sotelo & Palay 1970) in the lateral cervical nucleus of the adult cat (Westman, 1971) in the developing motoneurons of the spinal cord (Conradi & Skoglund, 1969 a) and in a three-dimensional study of two small cells in the lateral geniculate body of the adult rat (Karlsson 1966) In the present material the populations of various nerve endings on the giant and medium-sized neurons did not change during development, but slender terminals first appeared at the end of the first postnatal week on the cell bodies of giant and medium-sized neurons.

Interneuronal connections were scanty at the time of birth in neurons of all sizes in the lateral vestibular nucleus, although all the neuronal surfaces were tightly packed with endings The small neurons differed markedly from the larger ones, also with regard to the development of synaptic connections In newborn animal the small neurons were covered by a homogeneous population of synapsing endings, consisting only of small axon terminal These increased in number during the first few postnatal days and were still sparse at the adult stage as previously reported in the lateral vestibular nucleus of the adult rat (Sotelo & Palay 1970)

In the larger neurons, synapt c connections were regularly formed throughout the

The third kind of axo-a onal synapses were axon terminals synapsing on the axon hillock or the initial segment f an axon extending from a neuron. Criteria for the identification f both the axon hillock and the initial axonal segment in mature nervous tissue ha been gi en by Palay et l. (1968) and the morphology and synaptology of these structures ha lso been described in detail in certain other reports (Peters et al 1968 Conradi, 1969 b) including investigations f th lateral estibular nucleus f the adult rat (Sotelo & Palay 1968) The early stages of development of the xon hillock and in tial segment ha e been studied even less than the mature structures (Kornguth et al., 1968 Conradi & Skoglund, 1969 b). In their three-dimensional studies of the development f the initial motoraxon segment in the lumbosacral spinal cord, Conradi & Skoglund (1969 b) showed that the axo-axonal synapses on the initial motoraxon segment disappeared during the first three weeks f postnatal lif In the present materi l, too, both the axon hillock and initi l axonal segment were tightly covered by synapsing terminals f arious sizes during the first postnatal week, but the synaps g nerv ending covering on the initial segment was scanty in the adult animals

The ident fication f the axon hillock and initial segment was a greater problem in the developing Deiters nucleu than in th l mbosacral cord owi g to the bsence of myelination in axons sent ff by neurons, in any event during the first postnatal week Axons running from giant neurons into myelin sheaths were only seen in adult animals, nd th axon h llock region could not be identified in the preceding tw ge groups The few proximal axonal prof les identified in the arious ge groups studied during the first postnatal week resembled the proximal axonal profiles f the motoneurons in the neonatal tage described by previous investigators (Conradi & Skoglund, 1969 b) except that the initial segment la ked a gra ular membrane specialization However according to Sotel & Palay (1968) there is no gran lar membrane specialization under that part of the cytomembrane that lies opposit the synaptic terminals On the other hand, the present m terial the axon hillocks nd initial segments in adult animals corresponded completely to the descriptions of previous authors (Palay et al 1968)

DEVELOPMENT OF VARIOUS KINDS OF AXON TERMINALS

The complexity f the interneuronal relationships in the lateral vestibular nucleus f the rat is brought out by the variations in ultrastructure of the nerve endings and their specialized cell junctions A clear distinction of two types f synaptic junction as suggested by Gray (1959 1961) could not be m de in Deiters' nucleus in the rat, nor as it possible to classify the synapses into symmetric nd asymmetric as suggested by Gray & Guillery (1966). The same was found with regard to the synapses in the lateral estibula nucleus f the cat (Mugnaini et al 1967 b)

The different types f axon termin ls classified accord ng t Sotelo nd P lay (1970) were quite readily distinguished even in the early postnatal period, lthough they were more like t this time than at later stages f development. Small-sized large terminals were not only larger, they were lso more elongated, contained a greater amount of cell organelles and their syn ptic area wa shorter than large-sized small terminals

remained clearly higher in this location than on the cell bodies of giant neurons. Similar results were obtained in quantitative studies of the ending covering in single sections and in three-dimensional reconstructions of serial sections of developing motoneurons in the spinal cord (Conradi & Skoglund 1969 a). All types of axon terminals found in the adult rat (Sotelo & Palay 1968) were represented from birth on the proximal parts of dendrites of various calibres in neurons of all sizes in the present material. No quantitative or qualitative differences in the ending covering were observed between the dendrites sent off by neurons of different sizes. In this respect the results of the present investigation differed from the results obtained in the lateral cervical nucleus of the adult cat, in which the ending covering on the dendrites of small neurons was lower than that of the larger neurons (Westman, 1971).

All kinds of axon terminals synapsed in great number on the proximal parts of the dendrites of the newborn rat, including both types of slender terminals, but were rare on the distal parts of the dendrites during the first postnatal week. These observations were in agreement with the results recently reported in other parts of the central nervous system, where the first synaptic complexes in nerve cells have been observed in the proximal parts of dendrites (Bodian 1966, Schwartz et al. 1968). Moreover in the cerebral cortex (Schwartz et al. 1968, Meller et al. 1968, Adinolfi 1971 b), in the spinal cord (Bodian, 1966, Bunge et al. 1967) and in the cerebellum (Larramendi, 1967) axo-dendritic synapses were found to develop earlier than axo-somatic synapses.

Axo-axonal synapses

Throughout the postnatal development of the lateral vestibular nucleus the same three kinds of axo-axonal synapses were observed as have previously been described in the lateral vestibular nucleus of the adult rat (Sotelo & Palay 1970). Firstly, small axon terminals synapsed on large axon terminals, which were themselves presynaptic to the neuronal cell body or the proximal part of a dendrite. Axo-axonal synapses of this type were few in number at the newborn stage, but they clearly increased in number up to the tenth postnatal day, when they were as numerous as in adult animals. As judged by the location of the synaptic vesicle triangle, the direction of impulse transmission would be from the small to the large ones at all stages of development. In the central nervous system small axon terminals of this type, which were presynaptic to other axonal synapsing endings on the cell bodies or dendrites, have generally been considered as inhibitory (e.g. Eccles, 1964, Gray 1962).

Another type of axo-axonal synapses, already observed at the newborn stage some distance from the neuronal cell bodies and their processes, consisted of an axon terminal in contact with an adjacent axon. These axo-axonal synaptic contacts were most often seen in the first two age groups studied. During the early postnatal period they clearly decreased in number. At the end of the third postnatal week these axons began moreover to synapse on adjacent dendrites. At the end of the first postnatal month they formed fully developed axo-dendritic synaptic complexes, previously described in the lateral vestibular nucleus of the adult rat (Sotelo & Palay 1970), in the cerebellar cortex (Gray 1961, Palay 1961) and in the lateral geniculate body (Peters & Palay 1966).

coincides, the possible existence of desmosomal junctions unrelated t the occurrence f synaptic vesicles, in addition t synaptic junctions, may be a source of error in the interpretation f pictures of immature tissue (Bunge et al 1967 Aghajanian & Bloom, 1967). The present results aff rd no clue t the question of whether membrane thickenings precede the accumul tion f sy aptic vesicles.

POSTNATAL DEVELOPMENT OF GLIAL CELLS AND THEIR RELATIONS TO NEURONS

Throughout the postn tal development of Deiters nucleus it was no major problem to distinguish between tw lines f glial cells, an astrocytic and an oligodendrocytic line The precursors of astrocytes observed t the earlier developmental stages were called "light glial cells the precursors f oligodendrocytes dark glial cells ; Since the purpose was t elucidat the relations between gli l cell nd neurons from the tandpoint of the development f the nucleus, it was not considered necessary to discriminate precisely between d fferent stages f maturation f the glial cells. Previously too, only the astrocytic or oligodendrocytic nature of these cells has been established in studies f the early postnatal stages of development. Hardly any ttempts ha been made t identify the arious transitional forms of the respecti precursors in the central nervous system, which is even more difficult (Vaughn, 1969)

During the early post atal period dark glial cells with few processes were observed in small groups more distantly in the neuropil, wh le light glial cells with umerous slender extensions usually occurred n gly close to neurons From the new born stage, they were satell tes t neurons. These respecti features, sometimes even in more pronounced form, were typical f the two types f glial cell throughout the postnatal development f the nucleus until the adult stage. The total number of both astrocytes and oligodendrocytes increases during the f rst three postnatal weeks, fter wh ch slight decrease obviously occurs These conclusions were drawn from counts f precursors of v rious stages made on light micrographs mitoses were not observed either light microscopically or electronmicroscopically The results of the present study re in agreement with the observations mad in other parts of the entral nervous system (Fleischhauer 1968 V ghn, 1969) The rel ti proportions f astrocytic nd oligodendrocytic glial cells lso rem ined quite constant d ring post natal l f except f the end f th f rst postnatal week, when the formation of new glial cells of the astrocytic line was bunda t. At the time of formation these new glial cells differed morphologically from the remainder of the astrocytes on the light microscopic lev l, although not on the fine structural level and after a few days no major differences were observed in either the light microscope or the electron microscope The production of astrocytic glial cells has been found to be most intensive during the f rst postnat l week in other parts f the central nervous system, too (e g. Smart & Leblond, 1961 Vaughn, 1969) On the basis f the present study it is not possible to say whether these glial cells are produced in the lateral vestibular nucleus or in some other sit but their greater frequency in the dorsal part f the nucleus may indicate that they migrat from the ependymal layer f the fourth brain ventricle.

It has been shown by ma y investigators (e g M t rana, 1960 Peters 1960 Bunge et l 1962 Peters, 1964 Kruger & Maxw ll, 1966 Hirano et al 1966 Bunge,

All the different axon terminals increased in size throughout the postnatal developmental period until the adult stage. The most common cell organelles — mitochondria, neurofilaments, microtubules and tubules of endoplasmic reticulum — increased in number in all axon terminals throughout the postnatal period of development. The increase started earlier and was more accelerated in the large terminals than in the slender and small terminals, which developed more slowly in other respects, too. The number of agranular synaptic vesicles per terminal also rose throughout the period of postnatal development in all nerve endings, although most clearly in the large and slender terminals. By contrast, the number of granular vesicles increased only in the small endings; in the remainder of the terminals it decreased.

Simultaneously with the increase in synaptic vesicles, the number of both synaptic and desmosomal junctions in the junctional zones increased in the large and slender terminals. The synaptic junctions in the slender terminals on the neuronal bodies in particular increased rapidly in number during the second postnatal week, reaching the adult level in a few days. The presence of a great number of granular vesicles in the large endings on the first postnatal days and their almost complete disappearance at later stages was an interesting finding, especially considering that these vesicles are probably not related to catecholamines (Fuxe 1965). Granular vesicles in the slender terminals decreased strikingly in number with advancing development. In the small axon terminals vesicles of this kind were not observed until the fourth postnatal day, but from this stage they were a constant finding, and their number per small terminal increased throughout the postnatal development. At the adult stage these vesicles were obviously typical of the small nerve endings.

Junctional zones, both synaptic and desmosomal junctions, were observed in the large terminals in newborn animals. Pre- and postsynaptic membrane thickenings resembling desmosomal or future synaptic junctions without synaptic vesicles were occasionally seen in the large nerve endings. There was no clearly synaptic junction between these and the cell body in the same plane of a section. Without serial sectioning it is, however, impossible to identify these junctions. All symmetrical membrane thickenings without adjunct synaptic vesicles were considered to be desmosomal junctions, but a proportion of them may have been developing synaptic junctions, in which the pre- and postsynaptic membrane thickenings developed before the accumulation of synaptic vesicles on the presynaptic membrane thickenings.

The third type of junctional zone, the gap junction, first demonstrated by Sotelo and Palay (1967, 1970) between synaptic endings and mammalian nerve cells in the lateral vestibular nucleus and considered by these authors to be a constant element of large terminals, could not be identified with certainty in the present material, possibly because of the fixation used (Sotelo & Palay 1970). If junctions of this type occurred, they were probably regarded as desmosomal.

The formation of synapses has been the object of numerous investigations (e.g. Bunge et al. 1967, Tennyson 1970). Many authors have reported that local thickenings of adjacent pre- and postsynaptic plasma membranes are the first sign of specialization, and that the accumulation of synaptic vesicles occurs later. In the adrenal medulla (Hervonen 19[illegible]1) and the myoneural junction (Teravainen 1968) the accumulation of vesicles is reported to precede the postsynaptic thickening. Since the most intensive phase in the formation of both synaptic and desmosomal junction

SUMMARY

The postnatal development of the lateral vestibular nucleus (Deiters' nucleus) of the rat was studied by both light and electron microscopy in adjacent sections in seven age groups, from the newborn to the adult stage.

The neurons were divided into three groups (giant, medium-sized and small) which differed with regard to postnatal growth and differentiation. Their nuclear size did not increase after birth in any group. The postnatal development of the giant and medium-sized neurons had many features in common. They grew most during the first fortnight and had attained adult size by the end of the first postnatal month. The rough endoplasmic reticulum and the free ribosomes and Golgi membranes became organized and increased markedly in amount before the tenth postnatal day. Neuroplasmic filaments and tubules mainly increased in amount during the second and third postnatal week. The size of the small neurons increased only slightly during the first postnatal week. They had scanty rough endoplasmic reticulum and communications between the nuclear envelope and subsurface cisterns existed even in the adult animal.

All components of the neuropil, including the dendrites and axons and glial cells and especially the processes sent off by the astrocytes, increased more in size and amount than the neuronal cell bodies. Hence, the area of the neuropil increased in size more than that occupied by the neuronal perikarya.

Most of the growth of the axons of various sizes took place during the first postnatal week before the onset of myelination. Myelination started at the end of the first postnatal week but the most intense phase of myelination was observed during the second and third postnatal weeks. Partially myelinated small axons were still found in the adult nucleus. Degenerative changes in axons and their terminals, possibly representing axonal remodelling in normal nervous tissue, were observed in the mature or nearly mature nucleus.

The dendritic tree of all neurons developed mainly during the first postnatal week, although continued growth was still clearly observed during the second week. The dendritic tree of the giant neurons increased most in size. The dendrites sent off by neurons of different sizes during the early postnatal period differed only with regard to their content of cytoplasmic organelles. These were more abundant in the dendrites coming from the larger neurons than in the dendrites sent off by the small neurons.

The neurons of various sizes differed with regard to nerve ending covering, and the differences remained the same throughout the postnatal development. The only

1968) that oligodendrocytes form the myelin sheaths of the central nervous system and that the production of these cells is highest before the onset and during the course of myelination. In the present study, too, the formation of new glial cell of the oligodendrocytic line was found to be most intensive during the second and third postnatal weeks, in the areas showing early myelination. On the tenth postnatal day oligodendrocytes were clearly more numerous than astrocytes, and the ratio of the two types of glial cell was then about the same as in adult animals. From this age the majority of the astrocytic glial cells and an increasing proportion of the cells of the oligodendrocytic line resembled mature or almost mature astro- or oligodendrocytes with regard to fine structure, and precursors of both types decreased correspondingly in number, although their presence even at the adult stage indicated continued production of glial cells.

The glial cells of the astrocytic line representing various stages of maturation all formed cytoplasmic extensions into the surrounding neuropil and round the neurons and their processes, just as has been described in other parts of the central nervous system (e.g. Mugnaini & Walberg, 1964; Fleischhauer, 1968). The oligodendrocytes also had relatively prominent cytoplasmic processes at the immature stages preceding myelination of the nucleus. This finding was in agreement with the observations previously reported in the developing optic nerve of the rat (Vaughn, 1969). However the processes sent off by the astrocytic glial cells were much longer and more numerous from birth. Moreover, they increased markedly in number throughout the postnatal development.

The relations between neurons and neuroglial cells in Deiters' nucleus attracted attention when Hydén and his co-workers started investigating the neurochemistry of the nucleus. In a series of studies they advanced the interesting theory that a symbiotic relationship exists between neurons and neuroglial cell (e.g. Hydén, 1960; Hydén & Pigon, 1960; Hamberger, 1963). In these investigations it was stated that the cells in the lateral vestibular nucleus of the rabbit surrounding the neurons as satellites are mainly oligodendrocytes, and that the proportion of astrocytes in the close vicinity of neurons never exceeds 10 per cent of the neuroglia. These results are not corroborated by the observations made in the present study, which are in agreement with previous reports on the lateral vestibular nucleus of the adult rat (Sotelo & Palay, 1968) and the adult cat (Mugnaini et al., 1967 b). In the present material astrocytes were seen surrounding the neurons from birth, and the oligodendrocytes were located more distantly in the neuropil throughout the period of postnatal development. Oligodendrocytes were also observed in the vicinity of the smaller neurons, in particular, especially in myelinated areas. Thus the observations made on the postnatal developmental stages also indicated that the true satellites to neurons in the lateral vestibular nucleus of the rat are astrocytes. This conclusion is consistent with recent reports on other parts of the central nervous system, in which astrocytes were found to be satellites to large neurons, for instance to the Purkinje cells in the cerebellar cortex (Mugnaini & Forstrønen, 1966) and, besides oligodendrocytes, to the motoneurons in the lumbosacral spinal cord (Conradi, 1969 a; Conradi & Skoglund, 1969 a).

SUMMARY

The postnatal development of the lateral vestibular nucleus (Deiters nucleus) of the rat was studied by both light and electron microscopy in adjacent sections in seven age groups, from the newborn to the adult stage.

The neurons were divided into three groups (giant, medium-sized and small) which differed with regard to postnatal growth and differentiation. Their nuclear size did not increase after birth in any group. The postnatal development of the giant and medium-sized neurons had many features in common. They grew most during the first fortnight and had attained adult size by the end of the first postnatal month. The rough endoplasmic reticulum and the free ribosomes and Golgi membranes became organized and increased markedly in amount before the tenth postnatal day. Neuroplasmic filaments and tubules mainly increased in amount during the second and third postnatal week. The size of the small neurons increased only slightly during the first postnatal week. They had scanty rough endoplasmic reticulum and communications between the nuclear envelope and subsurface cisterns existed even in the adult animal.

All components of the neuropil, including the dendrites and axons and glial cells and especially the processes sent off by the astrocytes, increased more in size and amount than the neuronal cell bodies. Hence, the area of the neuropil increased in size more than that occupied by the neuronal perikarya.

Most of the growth of the axons of various sizes took place during the first postnatal week before the onset of myelination. Myelination started at the end of the first postnatal week but the most intensive phase of myelination was observed during the second and third postnatal weeks. Partially myelinated small axons were still found in the adult nucleus. Degenerative changes in axons and their terminals, possibly representing axonal remodelling in normal nervous tissue, were observed in the mature or nearly mature nucleus.

The dendritic tree of all neurons developed mainly during the first postnatal week, although continued growth was still clearly observed during the second week. The dendritic tree of the giant neurons increased most in size. The dendrites sent off by neurons of different sizes during the early postnatal period differed only with regard to their content of cytoplasmic organelles. These were more abundant in the dendrites coming from the larger neurons than in the dendrites sent off by the small neurons.

The neurons of various sizes differed with regard to nerve ending covering, and the differences remained the same throughout the postnatal development. The only

1968) that oligodendrocytes form the myelin sheaths of the central nervous system and that the production of these cells is highest before the onset and during the course of myelination. In the present study too the formation of new glial cells of the oligodendrocytic line was found to be most intensive during the second and third postnatal weeks, in the areas showing early myelination. On the tenth postnatal day oligodendrocytes were clearly more numerous than astrocytes, and the ratio of the two types of glial cell was then about the same as in adult animals. From this age the majority of the astrocytic glial cells and an increasing proportion of the cells of the oligodendrocytic line resembled mature or almost mature astro- or oligodendrocytes with regard to fine structure and precursors of both types decreased correspondingly in number although their presence even at the adult stage indicated continued production of glial cells.

The glial cells of the astrocytic line representing various stages of maturation all formed cytoplasmic extensions into the surrounding neuropil and round the neurons and their processes, just as has been described in other parts of the central nervous system (e.g. Mugnaini & Walberg 1964, Fleischhauer 1968). The oligodendrocytes also had relatively prominent cytoplasmic processes at the immature stages preceding myelination of the nucleus. This finding was in agreement with the observations previously reported in the developing optic nerve of the rat (Vaughn, 1969). However the processes sent off by the astrocytic glial cells were much longer and more numerous from birth. Moreover they increased markedly in number throughout the postnatal development.

The relations between neurons and neuroglial cells in Deiters nucleus attracted attention when Hydén and his co-workers started investigating the neurochemistry of the nucleus. In a series of studies they advanced the interesting theory that a symbiotic relationship exists between neurons and neuroglial cells (e.g. Hydén 1960, Hydén & Pigon 1960, Hamberger 1963). In these investigations it was stated that the cells in the lateral vestibular nucleus of the rabbit surrounding the neurons as satellites are mainly oligodendrocytes, and that the proportion of astrocytes in the close vicinity of neurons never exceeds 10 per cent of the neuroglia. These results are not corroborated by the observations made in the present study which are in agreement with previous reports on the lateral vestibular nucleus of the adult rat (Sotelo & Palay 1968) and the adult cat (Mugnaini et al. 1967 b). In the present material astrocytes were seen surrounding the neurons from birth, and the oligodendrocytes were located more distantly in the neuropil throughout the period of postnatal development. Oligodendrocytes were also observed in the vicinity of the smaller neurons, in particular especially in myelinated area. Thus the observations made on the postnatal developmental stages also indicated that the true satellites to neurons in the lateral vestibular nucleus of the rat are astrocytes. This conclusion is consistent with recent report on other parts of the central nervous system, in which astrocytes were found to be satellites to large neurons, for instance to the Purkinje cells in the cerebellar cortex (Mugnaini & Forstronen 1966) and besides oligodendrocytes, to the motoneurons in the lumbosacral spinal cord (Conradi, 1969 a, Conradi & Skoglund 1969 a).

and slender on terminals w th numerous activ zones and the number of desmosomal junctions increased in larger ones

Oligodendrocytes were in the m j rity among the glial cells during almost the hole development. Astrocytes were more or equally numerous only at the end of the first postnatal week, when the production of new astrocytes was strikingly abundant From the onset f myelination the oligodendrocytes increased more rapidly in number than the astrocytes, particularly at the beginning of the second postnatal week By the tenth postnatal day mature or nearly mature glial cells of both types were ery numerous In the subsequent development of the glial cells a continued increase in astrocytic processes mainly took place.

Throughout the whole postnatal development the astrocytes were located closer to the soma f the neurons than the ol godendrocytes. They were in wide direct contact w th these by their numerous extensions. The oligodendrocytes were generally located t a greater distance from th neurons. They were invari bly separated from the neurons by astrocytic processes. From birth to the adult tage astrocytes were true satellites to neurons in the lateral estibular nucleus of the rat

exception was that two types of slender terminals appeared on the perikarya of the giant and medium sized neurons at the end of the first postnatal week.

The development of axo-somatic synapses was similar in the giant and medium-sized neurons, although these contacts were established somewhat later in the latter group. From the newborn stage the large axon terminals were the first to synapse on both giant and medium-sized neurons. These synapses did not later increase in number per cross section of either type of neuron. The axo-somatic synapses increased most in number during the first postnatal week. This increase was mainly due to a multiplication of the synapses formed by small terminals, in particular in the giant cells. The same trend was observed in the giant and medium-sized neurons at the beginning of the second postnatal week simultaneously with an increase of both types of synapsing slender terminals. The axo-somatic synaptic connections of both types of neuron were most numerous on the tenth postnatal day. Later their number remained the same or decreased slightly. Only small axon terminals synapsed on small neurons. These synapses increased in number only during the first postnatal days and remained low during the later postnatal development.

All types of axo-dendritic synapses on the proximal parts of the dendrites were numerous from birth. The moderate increase in the number of axo-dendritic synapses on the proximal parts of dendrites observed during th first postnatal week was mainly due to an increase in the synapses made by small terminals. During the first and second postnatal weeks the number of synapsing small terminals increased more on the distal parts of the dendrites than on their proximal parts. New synaptic connections with the terminal segment of the dendrites seemed to develop even at the adult stage in dendritic expansions.

Axo-axonal synapses consisting of small axon terminals synapsing on large axon terminals, which were presynaptic either to the neuronal soma or the proximal part of a dendrite, increased in number up to the tenth postnatal day.

Axo-axonal synapses between axon terminals and axons of various sizes were seen in relative abundance in the neuropil during the early neonatal period. They rapidly decreased in number being rare at the tenth postnatal day and thereafter. Towards the end of the first postnatal month these synapsing axon terminals also began to synapse on adjacent dendrites, forming axo-dendritic synaptic complexes.

During the first postnatal week the number of axo-axonal synaptic terminals was high on both the axon hillock and the initial axonal segment, but in the latt r it their number reduced during later postnatal development.

From the newborn stage the axon terminals of various kinds to a considerable degree resembled the corresponding structures in the mature nucleus with regard to shape size contents and junctional zones. The terminals of all different types increased in size throughout the period of postnatal development but the large axon terminals and the two types of slender terminals increased considerably more in iz than the small terminals. The common cytoplasmic organelles, such as mitochondria neurofilaments and microtubules, increased in amount in all nerv endings throughout the postnatal development. The amount of granular synaptic esicles increased in the large and the two types of slender terminals, but not in the small terminals, which in turn had increasing amounts of granular vesicles. The number of synaptic junct ons per terminal rose relatively evenly throughout the postnatal development in l rge

ACKNOWLEDGEMENTS

The subject of the present study was proposed in 1968 by Professor Olavi Eränkö, M.D. Ph.D. Head of the Department of Anatomy University of Helsinki. I am deeply indebted to him for placing the facilities of the Department at my disposal. I wish to express my gratitude to Professor Eränkö for his interest, encouragement and support in the course of the present study.

I am greatly obliged to Docent Heikki Teräväinen, M.D. and Docent Aarno Kohonen, M.D. for reading the manuscript, for their readiness in advising me and for their valuable criticism.

My sincere thanks are due to all my colleagues in the Department of Anatomy in particular to Professor Arto Palkama M.D. to Dr Aulikki Kokko-Cunningham, M.D. to Professor Martti Kormano M.D. and to Dr Boris Kock, M.D. I wish also to express my appreciation to Docent Leena Rechardt, M.D. for her valuable aid in many phases of the study.

I am grateful to the members of the staff of the Department of Anatomy for their friendly and always helpful attitude. I wish to thank especially Mrs. Tuula Stjernvall for preparing the electron microscopic specimens, to Mrs. Liisa Kangasvuo Mrs. Paula Hasenson and Miss Raisa Mannikkö for their skilful technical assistance and Miss Helmi Palomäki for collecting literature.

To Mr Paavo Korhonen Head of Photography at the Institute of Photography University of Helsinki and to Mr Eero Ahti I wish to express my thanks for their co-operating in preparating the prints.

Mrs Eva Palmgren M. A. translated the text into English, and Mrs Susan Sirisalo B.A. checked the manuscript. I thank them for their fine collaboration.

Finally I thank my wife Ulla for her support throughout the course of my work.

Helsinki May 1975

I Hereditary and Clinical Aspects

Abstract. The coat colour, hair length and iris colour characteristics and the incidence of hereditary deafness are described for a population of 96 cats. The incidence of inner ear degeneration varied from 20 % to 86 %, being dependent on the genetic composition of the population under consideration. The scope of further publications on hereditary deafness in the white cat is outlined.

Anomalies of pigmentation are often found in association with hereditary deafness in several animal species and man. Waardenburg (1951), in the first definitive description of the syndrome which now bears his name, described the occurrence in man of congenital deafness and pigmentary defects of the iris and head hair. This syndrome was found to constitute a well demarcated genetic complex with an autosomal dominant inheritance (Cotterman, 1951). Several authors (Fisch, 1959; DiGeorge et al., 1960) have reported regions of cutaneous depigmentation as a fairly frequent feature of the Waardenburg syndrome. Ziprkowski et al. (1962) reported a family in which deafness and pigmentation anomalies were inherited through a sex linked recessive gene. Other differently inherited syndromes in which deafness is associated with varying degrees of hypopigmentation have been described by Tietz (1963) and Woolf et al. (1965).

Among animals, the most widely recognised species affected by these traits is the white cat, but several species of dog present hearing loss and pigmentation abnormalities due to the influence of the merle gene. This has been described in bull and fox terriers (Wright, 1918), collie dogs (Mitchell, 1935) and the Norwegian dunker hound (Sorsby & Davey, 1954). The dalmatian is not a merle dog, though also affected by hereditary deafness. Other animal species in which similar syndromes are found are the white mink (Sugiura & Hilding, 1970), the rabbit (Nachtsheim, 1941) and several genotypes of mice (Deol, 1970).

It is important in this context to differentiate between albinism and the white spotting or hypopigmentation which is the abnormality found in all the above mentioned species. In the former condition melanocytes can be identified in the skin as clear cells, or amelanotic melanocytes, but do not possess the ability to produce pigment (Billingham & Silvers, 1960). In the white areas of hypopigmented animals, however, melanocytes cannot be demonstrated although pigment is found in the retina (Markert & Silvers, 1956), showing that the capacity to produce pigment is retained by the animal. Albinos are completely devoid of pigment, but generally have normal hearing, although Margolis (1962) and Ziprkowski & Adam (1964) have described recessive albinism and deafness in man.

The difficulties encountered in differentiating between hereditary and acquired forms of deafness in man have been frequently stressed in the recent literature (Altmann, 1964; Lindsay & Matz, 1966) and it has been conclusively demonstrated that the Scheibe or cochleo-saccular type of inner ear degeneration can occur in both aetiological groups (Schuknecht, Igarashi & Gacek, 1965). It was hoped that a detailed investigation of the hereditary form of deafness in the white cat might give additional information helpful in the solving of problems of aetiology in human deafness. For maximum clarity and conciseness in the presentation of the results it was decided to group the material in separate publications, viz., heredity, development of the vestibular degeneration, maturation of the cochlea in normal hearing animals, development of the cochlear degeneration, degeneration of the

first order cochlear neuron and finally the findings in the primary cochlear nuclei The details of the relevant material and methods will be presented in each subsequent publication

MATERIAL AND METHODS

A white cat stock of 110 animals was gradually accumulated over a number of years. This population consisted partly of white coat adult animals received fortuitously in the animal quar ters, and of an approximately equal number of animals, both white and colour coat, bred from white cats already in our possession

The investigation commenced in 1964 with the acquisition of a pair of white cats The male member of this pair Romeo was used for breed ing purposes, first with the other original animal Juliet and subsequently with a number of other animals including his own offspring. In addition four adult white cats of known heredity were obtained from the National Institute of Health Washington. These two sources accounted for approximately half of the white cat stock the remainder being of unknown heredity and ac quired from a variety of sources. The original stock of 110 animals was reduced to 96 due to premature death or escape from the animal quarters Temporal bone histology was available for all these 96 animals.

The coat colour was recorded in all animals and the coat length in the majority Animals with the least admixture of colour in the coat were classified as non-white or coloured Hair length was readily classifiable as either long or short Coat colour and hair length could be assessed from birth. Iris colour was also evalu ated and recorded as blue i e completely blue iris without admixture of other colours, or as yellow in which group yellow green brown and all forms of heterochromia were included As all kittens have blue eyes in the early post partum stage before the eyes open spontaneously it was not found possible to make a reliable estimate of eye colour earlier than fourteen days of age

The cochlear potentials were recorded from round window electrodes in all animals and vestibular testing performed in approximately one third. Heidenhain s Susa fixative was used for intravital perfusion throughout the series and the temporal bones and hind brains were removed usually in separate blocks and processed for histological examination with the light microscope Animals were sacrificed at ages varying from a few hours after birth up to approximately eight years of age. It was found that the presence or absence of hearing could not be established with certainty prior to the seventh day post partum. The earliest reliable light microscopical evidence of end organ degenera tion was also found after seven days of age. Therefore, in this series, the presence or absence of hearing and of histological inner ear degeneration have been established only for animals more than one week old

RESULTS

The age distribution of the 96 animals in the white cat stock is shown in Table 1 The associa tion between coat colour and inner ear degener ation in the 76 animals over the age of one week is shown in Table 2. All of the coloured coat animals had bilaterally normal hearing and temporal bone histology apart from the occa sional presence of middle-ear infection Inner ear degeneration and absence of the round win dow potentials were found in 34 of the 66 white coat animals (51 5 %) being unilateral in eight (12.2%) The data on coat length are unfor tunately incomplete there being no record in 15 of the 66 white coat animals. Table 3 shows the association between coat length and inner

ear degeneration. 79 % of the long coat animals had degeneration in one or both ears as against only 33 % of the short hairs. However animals with short hair accounted for [illegible] % of the unilateral degeneration group, whereas short hair was present in only 19 % of those with bilateral inner ear degeneration.

Eye colour was recorded for all of the 58 white coat animals over the age of 14 days (Table 4). Inner ear degeneration was present in 85 % of blue-blue animals, in 40 % of blue yellows and in only 16.7 % of yellow yellows. Of the 58 animals in this group 20 had bilateral and 8 unilateral inner ear degeneration. Degeneration was therefore present in 48 of 116 ears. The association between inner ear degeneration and ipsilateral eye colour is shown in Table 5. Blue eye colour is again shown to be more frequently associated with inner ear degeneration than is yellow (38 10). The eight unilaterally deaf animals are presented in Table 6. This shows a

negative correlation for blue eye colour on the contralateral side, i.e. if the ipsilateral eye colour is yellow then the contralateral is not blue. The data for eye colour and coat length are combined in Table 7. Inner ear degeneration was present in all four of the blue-blue-shorts and in 11 of the 12 blue-blue-longs. Both of the yellow-yellow-longs had hearing bilaterally.

In Fig. 1 are presented the results of mating one of the animals, Romeo, with various females, including one of his own offspring, Euridice. Unfortunately, several of the temporal bones from this group were not available for histological examination due to premature death. None of the colour coat animals had blue eyes or inner ear degeneration. The mating of Romeo and Princess, both bilaterally deaf animals, produced five offspring, three with bilateral inner ear degeneration, but the remaining two were unfortunately sacrificed at an age when hearing could not be reliably assessed. The material is therefore inadequate for a proper investigation of the penetrance of the gene for deafness.

The distribution of inner ear degeneration in the different heredity groups is shown in Table 8. There were 66 white coat animals of more than seven days of age which gives a total of 13 ears. Inner ear degeneration was present in 60 of those ears, 26 animals having bilateral and 8 unilateral degeneration. The incidence of inner ear degeneration in the population as a whole is therefore 45.4%. When only Romeo's descendents are analysed the incidence of inner ear degeneration is 86%, whereas the figure for the presumably heterogeneous group of animals of unknown heredity is 20.3%.

DISCUSSION

The association between white coat colour, blue iris colour and deafness in cats was regarded as invariable by the earliest observers (Bree, 1829; Sichel, 1847; Darwin, 1859). However Tait (1883) reported that deafness could occur either with blue or yellow eye colour, but believed that only white coat males were affected. Stevens (1884) disagreed with the latter finding and reported the occurrence of deafness in blue-eyed, white coat females. Przibram (1907) concluded that the hearing loss was always on the side of the blue eye in animals with different eye colours, a finding which is corroborated by our series of unilaterally deaf animals. Beaumont (1911) found the association between blue eye colour and deafness to be constant, and believed that animals with only one eye blue were never deaf. The same author also reported blue-eyed offspring amongst the descendents of animals with bilateral yellow eye colour. Breeding experiments carried out by Whiting (1918) established that white coat colour was inherited as a Mendelian dominant, but that the inheritance of iris colour was very irregular. Wright (1918) and Bamber (1927) found a tendency for asymmetrically coloured eyes to run in families, but the asymmetry was unspecific and the mode of inheritance unknown.

The earlier literature therefore contains many contradictory statements, but unfortunately many of the later contributions have not helped appreciably to clarify the situation. The literature of recent years contains a few reports on deafness in the white cat, with descriptions of only the physiological and histological findings for short series of three or four animals (Wolff

1942; Wilson & Kane, 1959; Suga & Hattler, 1970). Only two publications contain studies of larger series, both, however, being confined to younger animals (Bosher & Hallpike, 1965; Bergsma & Brown, 1971).

Bosher & Hallpike (1965) reported a series of 28 white cats, but eye colour and coat length were not mentioned and the oldest animal was sacrificed at 281 days. Of the seven animals used for breeding purposes, six were bilaterally deaf and the seventh had unilateral ear degeneration. The penetrance of the inner ear degeneration in that series was about 80%. More recently Bergsma & Brown (1971) in a comprehensive genetic study of young animals found that blue eye colour tended to be bilateral and that heterochromia in parents did not predispose to heterochromia in the offspring. Further, the autosomal dominant gene had complete penetrance for white coat colour, but the ear defect was only about 43% penetrant.

The present series supports the latter conclusions. The incidence of inner ear degeneration in the entire white cat population was 45.4%, whilst in the group of Romeo's descendents the penetrance of 86% is of the same order of magnitude as the 80% reported by Bosher & Hallpike (1965). In our heterogeneous white cat population the incidence of inner ear degeneration was 20.3% which is close to the penetrance of 27% reported by Bergsma & Brown (1971) for the heterozygote, and is identical to the penetrance of 20% reported for the inner ear degeneration in Waardenburg's syndrome (Fisch, 1959).

CONCLUSIONS

This material does not permit a detailed statistical analysis, but the following conclusions may be drawn.

1. Hereditary deafness in cats occurs only in animals with white coats.

2. Deafness may be unilateral or bilateral and is found in both sexes.

3. The inner ear degeneration is more often associated with blue eye colour, but the association is far from constant.

4. Animals with different eye colours may have either bilateral or unilateral degeneration, but in the latter case the degeneration is on the side of the blue eyes.

5. Long coat hair is more often associated with inner ear degeneration (79%) than is short hair (33%). The latter, however, is more frequently associated with unilateral hearing loss.

6. The incidence of inner ear degeneration in a random white cat population is 20.3%, but increases to 86% when hereditary hearing loss is present in one or both of the parents.

ZUSAMMENFASSUNG

Die Beziehungen zwischen Farbe des Pelzes, Haarlänge, Irisfarbe und erblicher Taubheit werden für eine Gruppe von 96 Katzen mitgeteilt. Das Auftreten von Innenohr-Degeneration wechselt von 20% bis 86%; es hängt von der genetischen Struktur der Population unter bestimmten Bedingungen ab. Es wird auf zukünftige Arbeiten über erbliche Taubheit bei der weissen Katze hingewiesen.

MATERIAL AND METHODS

A white cat stock of 96 animals was acquired over a number of years. Sixty-six of these animals had completely white coats and could be assessed for the presence or absence of hearing. Details of this population have been presented in part I of this volume (Mair I).

Vestibular testing was performed in thirty animals. Button electrodes were inserted at the glabella and in the malar bones for the electronystagmographic recording of horizontal eye movements. Posture, locomotion and righting reflexes were observed and positional, optokinetic, oscillatory and caloric tests performed. The investigational techniques have been described elsewhere (Mair & Fernández, 1966). The youngest animal in whom vestibular testing was performed was aged six months and the oldest was eight years of age.

Cochlear potentials were recorded from a round window electrode in all 96 animals. Bilateral hearing loss was found in 26 and unilateral in 8 of the white coat animals. The animals were then perfused by the standard intravital method of fixation using Heidenhain's Susa reagent, survival periods varying from the first postnatal day up to eight years of age. In the vast majority of cases the temporal bones and hind brains were removed in separate blocks and processed for light microscopy. The temporal bones were imbedded in celloidin and orientated with the midmodiolar axis of the cochlea in the horizontal plane. Serial sections were cut at a thickness of 20 microns and every tenth section stained with haematoxylin and eosin. The vestibular labyrinth was studied systematically and the findings in the deaf ears compared with age matched white coat hearing animals. For purposes of comparison, the temporal bones from 13 kittens and 10 adult cats from colour coat stock were examined for the distribution of pigment. The extent of pigmentation was recorded in each animal from the contra-macular wall of the utricle and from the slopes of the crista in each canal (Deol, 1970).

Table 9. *Age distribution and incidence of inner ear degeneration in the thirty white coat cats subjected to vestibular testing*

Inner ear degeneration	Age in months			Total
	6–11	12–24	24+	
Bilateral	3	4	7	14
Unilateral	1	2	1	4
Absent	0	0	12	12
Total	4	6	20	30

RESULTS

1. *Functional examination*

The complete battery of vestibular tests was performed in 30 animals. Subsequent measurement of cochlear potentials showed that 12 of the 30 had normal hearing bilaterally, 14 were bilaterally deaf and in 4 the hearing loss was confined to one ear. The incidence of inner ear degeneration and the age distribution of the 30 white coat animals tested are shown in Table 9.

No disorders of posture or locomotion were observed and the righting reflexes were normal for all 30 animals. The remaining 66 animals not subjected to the full vestibular testing procedure were, however, observed clinically and no disorders of equilibration could be ascertained in the course of the animals' normal range of activity. Positional nystagmus was neither observed nor recorded in any of the 30 animals tested. The optokinetic and rotatory responses were symmetrical and non-pathological. No abnormalities were detected on bithermal caloric irrigation (Fig. 2). Oscillation responses were also normal (Fig. 3).

2. *Histological examination*

The osseous labyrinth presented no abnormalities. The membranous labyrinth from all hearing ears, both from white coat and colour coat animals, was unremarkable. The membranous semicircular canals and the utricle of all deaf ears were of normal dimensions and the light-microscopical appearances of the neuroepithelium of the cristae and the utricular maculae were indis-

II Vestibular Function and Histopathology

Abstract An electronystagmographic study of vestibular function in the deaf white cat revealed no functional abnormalities. Histological changes were confined to the saccule and increased as a function of age. Collapse of the saccular wall was followed by encapsulation of the otolithic membrane. At all stages in the degenerative process the region of the saccule nearest the cochlea was more severely affected than the more posterior areas. The degenerative process extends radially from the ductus reuniens and shows no correlation with the degree of inner ear pigmentation.

The pars inferior of the membranous labyrinth appears to be more susceptible to a variety of nocuous agents than are the phylogenetically older utricle and semicircular canals The cochleo-saccular or Scheibe, type of inner ear degeneration has been described in hereditary human deafness (Scheibe, 1891 Ward et al 1962), in deafness due to maternal rubella (Lindsay et al., 1953) and in presumed viral labyrinthitis (Lindsay & Hemenway 1954 Lindsay Davey & Ward 1960) Cochleo-saccular degeneration has also been demonstrated in aged humans and animals (Schuknecht, Igarashi & Gacek, 1965) A similar type of degeneration has been found in several species of animals afflicted by hereditary deafness Among those species reported in the literature are the white mink (Sugiura & Hilding, 1970) several species of dog (Igarashi et al 1972) various mouse mutants (Deol, 1968) and the white cat (Bosher & Hallpike 1965)

The first description of the temporal bone findings in deaf white cats was that of Rawitz in 1897 but the condition of the vestibular organs was not mentioned Alexander (1900) reported similar cochlear findings, but noted in addition that the saccular wall was collapsed and that there was degeneration of the saccular macula The finding of cochleo-saccular degeneration in the deaf white cat has since been confirmed by several authors (Howe, 1935 Bosher & Hallpike, 1965 Suga & Hattler 1970), but several publications contain either contradictory statements or the results of inadequate investigations. Wolff (1942) stated that the 'vestibular end-organs and ganglion cells appeared to be in good condition in a deaf adult white cat. In three of the four temporal bones examined by Wilson & Kane (1959) no mention of the vestibular end-organs is made. The fourth is described as showing no obvious vestibular disturbances" A more recent publication on this subject (Suga & Hattler 1970) contains descriptions of the histological findings in three animals. All had normal utricles and semicircular canals, but obliteration of the saccular lumen with degeneration of the macula was found in two The saccule in the third animal a deaf adult, was reported as showing no abnormalities.

Hereditary inner ear degeneration has been most systematically studied in the mouse, in which species approximately thirty mutants with inner ear abnormalities have been investigated (Deol 1968) Most of these mutants have behavioural disorders known as the waltzing syndrome but considerable differences exist between the genotypes. The time course of the vestibular end-organ degeneration has been extensively studied in many of these mutants (Deol 1968)

The literature on vestibular findings in the deaf white cat contains no studies comparable to those in the mouse There are no reports on vestibular physiology and the development of the degeneration in the vestibular labyrinth has not been studied in any detail This paper contains the results of vestibular testing of a white cat stock and a detailed description of the light microscopical findings in the vestibular labyrinth from a series of deaf animals.

MATERIAL AND METHODS

A white cat stock of 96 animals was acquired over a number of years. Sixty-six of these animals had completely white coats and could be assessed for the presence or absence of hearing. Details of this population have been presented in part I of this volume (Mair I).

Vestibular testing was performed in thirty animals. Button electrodes were inserted at the glabella and in the malar bones for the electronystagmographic recording of horizontal eye movements. Posture, locomotion and righting reflexes were observed and positional, optokinetic, oscillatory and caloric tests performed. The investigational techniques have been described elsewhere (Mair & Fernández, 1966). The youngest animal in whom vestibular testing was performed was aged six months and the oldest was eight years of age.

Cochlear potentials were recorded from a round window electrode in all 96 animals. Bilateral hearing loss was found in 26 and unilateral in 8 of the white coat animals. The animals were then perfused by the standard intravital method of fixation using Heidenhain's Susa reagent, survival periods varying from the first postnatal day up to eight years of age. In the vast majority of cases the temporal bones and hind-brains were removed in separate blocks and processed for light microscopy. The temporal bones were imbedded in celloidin and orientated with the midmodiolar axis of the cochlea in the horizontal plane. Serial sections were cut at a thickness of 20 microns and every tenth section stained with haematoxylin and eosin. The vestibular labyrinth was studied systematically and the findings in the deaf ears compared with age-matched white coat hearing animals. For purposes of comparison, the temporal bones from 13 kittens and 10 adult cats from colour coat stock were examined for the distribution of pigment. The extent of pigmentation was recorded in each animal from the contra-macular wall of the utricle and from the slopes of the crista in each canal (Deol, 1970).

Table 9. *Age distribution and incidence of inner ear degeneration in the thirty white coat cats subjected to vestibular testing*

Inner ear degeneration	Age in months 6–12	12–24	24+	Total

Fig. Hot caloric responses from an adult white cat with bilateral cochleo-saccular degeneration showing period of maximal response. An upward deflection in this and the succeeding figure indicates horizontal eye movement towards the left and a downward deflection indicates similar movement to the right. Time marker = 1 second.

tinguishable from those of hearing ears. The canalicular and utricular nerves were unremarkable. Pathological findings in the vestibular labyrinth were confined to the saccule and occurred only in those ears shown to be deaf by cochlear electrophysiological studies. No histological abnormalities were found in animals of seven days of age or younger. The development of the saccular degeneration was found to be a function of increasing age.

The youngest animal with unequivocal hearing loss was aged eight days, and the only histological sign of vestibular abnormality at this stage is a change in the configuration of the lateral wall of the saccule. The anterior portion of the lateral saccular wall has a wavy outline and appears to be in the process of descending towards the macula (Fig. 4 A). At this stage the cochlear duct is of almost normal dimensions, but in the upper basal coil Reissner's membrane has a similar wavy outline although this is less pronounced than in the saccule (Fig. 4 A). Later stages of this process in adult animals are shown in Fig. 4 B and Fig. 5 D. The saccular wall is seen to be in contact with the full extent of the macula producing almost complete obliteration of the lumen. This latter is, however never complete as the posterior part of the saccular lumen always remains patent.

Once the process of saccular degeneration has commenced it proceeds very rapidly. At day eight the sensory and supporting cells of the saccular macula reveal no abnormalities and the sole pathological finding is the previously described change in the antero-lateral wall. At day ten the saccular wall has collapsed still further and is in contact with the anterior pole of the macula and of the otoconia layer (Fig. 5 B). The latter appears to have increased in thickness. The sensory cells at this stage appear mature and healthy and indistinguishable from a hearing animal of similar age but the hairs are deflected posteriorly and have assumed a position almost parallel to the free surface of the neuroepithelium. Two days later at day twelve the saccular wall is in contact with the entire extent of the otolithic membrane (Fig. 5 C). The individual otoconia are larger and have a more intensely basophilic stain. Between the free surface of the neuroepithelium and the deep surface of the otoconia layer and apparently applied to the latter a thin layer of flattened cells is found. The otoconia layer thus appears to be surrounded by a membraneous covering. The sensory cells still have a healthy appearance but there is a definite reduction in the number of hairs. A few free nuclei

are present in the space between the neuroepithelium and the membrane-enclosed otoconia.

The animals sacrificed at day twenty and day twenty-six both proved to have unilateral hearing loss, thus permitting direct comparison of the saccular findings in hearing and deaf ears at this important stage in the development of the degenerative process

A high-power view of the saccule from the healthy ear of the twenty day animal is shown in Fig 6 A, and a similar area from the opposite and deaf ear is presented in Fig 6 B. In the week which has elapsed from day twelve to day twenty the following changes have occurred in the saccule The otoconia layer is definitely thicker on the pathological side and the individual otoconia are larger and more basophilic staining. The saccular wall remains collapsed, but the membranous layer on the deep surface of the otoconia is more prominent and varies from one to two cells in thickness. Very few hairs can be identified on the free surface of the neuroepithelium and there is an appearance of vacuolisation in the supranuclear area of the sensory cells. The free nuclei

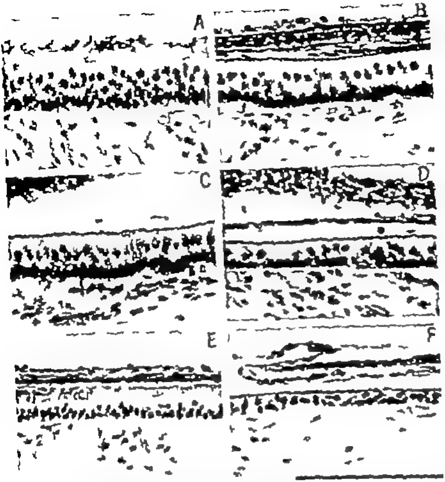

Fig. 6. Higher power view of saccular macula and otoconia layer from approximately the central portion of the macula in five white cat animals. Marker 50 microns. (A) Right saccule from unilaterally deaf animal aged 20 days showing normal appearance from the hearing ear. (B) Pathological left saccule from same animal shown in 5 A, from the opposite, deaf ear. Both surfaces of the otoconia layer are enclosed in cellular membranes. (C) Pathological left saccule of cat aged 26 days. The crenellated layer of globular vesicles projecting above the surface of the neuroepithelium can be identified. (D) Pathological right saccule from cat aged 43 days. The globular vesicles shown in 5 C are replaced by a layer of homogeneous, eosinophilic precipitate. The neuroepithelium is markedly reduced in height and there is reduction in numbers of sensory cells. (E) Pathological right saccule of animal aged 14 months. The layer of precipitate shows fragmentation and there is a much greater degree of sensory cell loss. (F) Pathological left saccule of adult cat aged 8 years. Sensory cells are absent and the supporting cells are degenerating with loss of cell outlines and pyknotic nuclei.

ly eosinophilic staining, amorphous precipitate which covers the entire surface of the macula. There is considerable sensory cell loss, most marked at the anterior pole and the height of the neuroepithelium is definitely reduced. Most of the remaining sensory cells have acuolated cytoplasm and there are many free pyknotic nuclei and degenerating cells present in the space between the macula and the otoconia layer.

From two to fourteen months the degenerative process consists of an increasing sensory cell loss and an increase in the membranous layers surrounding the otoconia. Specimens were available at six and ten months. The saccule from a fourteen month deaf ear is shown in Fig. 6 E. Three layers of flattened cells are present on the deep surface of the otoconia. Very few sensory cells remain, and these are found only at the posterior

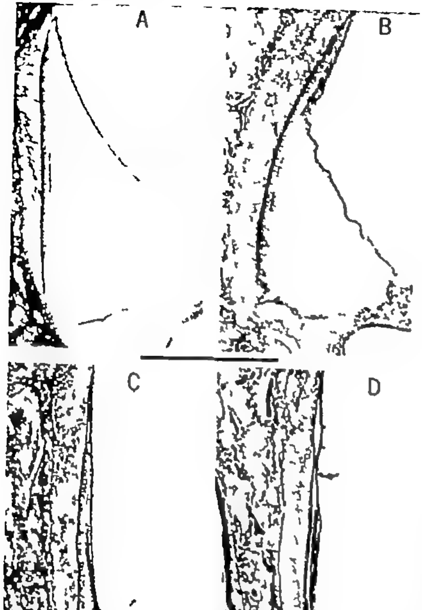

Fig 5 Low power view of the left saccule orientated with the anterior or juxta-cochlear pole superiorly Marker = 500 microns. pose, i.e. deaf ears in white coat animals, hearing ears in white coat cats and hearing ears in animals with coloured coats. In each group pigment accumulation varied from considerable to complete absence. There was, however, a tendency for pigment to increase in quantity with increasing age in all three groups. The distribution of pigment was symmetrical in the ears of all unilaterally deaf animals irrespective of age.

Two animals, aged respectively ten and fourteen months, presented a rather unexpected finding in the degenerating saccular macula. Two cells were found in the former and one in the latter which had the typical light microscopical appearance of ganglion cells from Scarpa's ganglion (Fig. 8). There was no evidence of ganglion cell loss in Scarpa's ganglion of deaf adult animals.

DISCUSSION

Vestibular studies in human hereditary deafness have generally shown normal function (Arnvig, 1955), but depressed responses have been reported in Usher's (Vernon, 1969) and in Pendred's syndromes (Fraser et al. 1960). In the family with partial albinism and deaf mutism reported by Ziprkowski et al. (196.) caloric testing revealed absent responses. Anomalies of pigmentation are also present in Waardenburg's syndrome and Marcus (1968) has shown that disturbances of vestibular function occur more commonly than does hearing loss. However tomography in two of his cases revealed cochlear and canal hypoplasia and absence of the posterior canal, whereas the sole report of the histological findings in this syndrome describes degeneration confined to the membranous pars inferior of the inner ear (Fisch, 1959).

Anomalies of locomotion accompany the hereditary inner ear degeneration in several mouse mutants (Deol, 1968), but locomotor abnormalities have never been described in man, cats or dogs (Altmann, 1964). The vestibular studies from the present series of deaf white cats have not revealed evidence of malfunction. Even adult animals with complete loss of saccular sensory cells have no demonstrable disturbance of voluntary or provoked eye movements, under the experimental conditions of this investigation, and this applies equally to unilateral and bilateral lesions.

Detailed studies of the time course of vestibular end-organ degeneration in hereditary deafness have been made only in the mouse. Degeneration of the saccular macula occurs considerably later than in the cochlea of these mutants (Deol, 1968). In the present white cat material, reduction of the saccular lumen and volume changes in the scala media of the cochlea occur simultaneously. The process of saccular degeneration commences at the anterior pole and a time lag was consistently found which became pro-

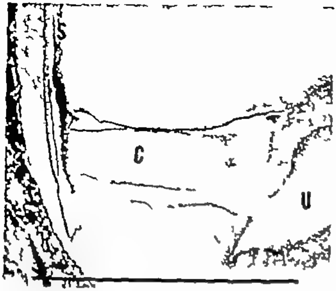

Fig 7 Left ear from 6 month bilaterally deaf white cat showing saccule (*S*), utricle (*U*) and the "cyst" formation (*C*) in the postero-superior corner of the saccular lumen Marker = *1 mm.*

or juxta-utricular pole of the saccule. Commencing degeneration of *the supporting cells is evident* and in some areas towards the anterior pole the layer of supporting cells is patchily absent. The uniform layer of eosinophilic precipitate found in the previous age group is now broken *up into localised accumulations of a more deeply* eosinophilic material A definite layer is found only at the posterior pole where sensory cells can still be identified

At twenty-one months further reduction in sensory cell numbers has occurred and there is little eosinophilic precipitate remaining. A very few sensory cells remain at the postero-superior corner of the macula. In the eight year-old adult (Fig. 6 F) the layer of deeply basophilic staining otoconia persists, apparently unchanged and remains enclosed in the cellular membrane. No sensory cells can be identified and the supporting cells are markedly degenerated the cell borders cannot be identified and the nuclei are pyknotic. There are many areas, especially towards the anterior pole where also the supporting cells are absent

Both the obliteration of the saccular lumen and the subsequent degeneration of the macula *first of the sensory cells and at a later stage, of* the supporting cells, commence at the anterior or cochlear pole of the saccule and extend successively in a posterior direction The posterior or juxta utricular part *of the saccular lumen is,* however never obliterated A constant feature which first makes its appearance at day twenty and thereafter persists throughout life is the appearance of a cyst-like formation in the pos*tero-superior corner of the saccular lumen.* A typical "cyst from a six month deaf cat is shown in Fig. 7 None of the hearing ears presented this finding. Study of consecutive sections has shown that the cyst" is formed by a herniation *medially and superiorly of the lateral saccular* wall into the patent postero-superior corner of the saccular lumen The structure is therefore cone shaped and communicates *laterally and* inferiorly with the perilymphatic space of the vestibule. Considerable variation in size was found the largest having a vertical height of 220 microns and the smallest about 60 microns. *The size of the cyst" was not related to the age* of the animal None of the specimens showed defects in the cyst" wall which would permit admixture of perilymph and endolymph and no adhesions were found between the "cyst" walls *and the inner* aspect of the saccule

The utriculosaccular duct and the ductus endolymphaticus were patent in all pathological ears The endolymphatic sac contained a variable amount of deeply eosinophilic staining *material but the picture was inconstant.* A ten month animal with unilateral degeneration showed considerable precipitate, especially in the rugose portion of the sac, but the amount and the staining characteristics were similar in both ears. *In the deaf adult animals the amount of* precipitate varied from slight through moderate to considerable No otoconia were found in the endolymphatic duct or sac and there were no significant differences in the dimensions of the vestibular *aqueduct and endolymphatic* ducts of pathological and normal ears. The lumen of the ductus reuniens was markedly reduced and often obliterated in the older pathological ears.

No differences were found in the amount or *distribution of pigment* in the vestibular labyrinth in the three groups studied for this pur

DISCUSSION

Vestibular studies in human hereditary deafness have generally shown normal function (Arnvig, 1955), but depressed responses have been reported in Usher's (Vernon, 1969) and in Pendred's syndromes (Fraser et al., 1960). In the family with partial albinism and deaf-mutism reported by Ziprkowski et al. (1962) caloric testing revealed absent responses. Anomalies of pigmentation are also present in Waardenburg's syndrome and Marcus (1968) has shown that disturbances of vestibular function occur more commonly than does hearing loss. However, tomography in two of his cases revealed cochlear and canal hypoplasia and absence of the posterior canal, whereas the sole report of the histological findings in this syndrome describes degeneration confined to the membranous pars inferior of the inner ear (Fisch, 1959).

Anomalies of locomotion accompany the hereditary inner ear degeneration in several mouse mutants (Deol, 1968), but locomotor abnormalities have never been described in man, cats or dogs (Altmann, 1964). The vestibular studies from the present series of deaf white cats have not revealed evidence of malfunction. Even adult animals with complete loss of saccular sensory cells have no demonstrable disturbance of voluntary or provoked eye movements, under the experimental conditions of this investigation, and this applies equally to unilateral and bilateral lesions.

Detailed studies of the time course of vestibular end-organ degeneration in hereditary deafness have been made only in the mouse. Degeneration of the saccular macula occurs considerably later than in the cochlea of these mutants (Deol, 1968). In the present white cat material, reduction of the saccular lumen and volume changes in the scala media of the cochlea occur simultaneously. The process of saccular degeneration commences at the anterior pole and a time lag was consistently found which became pro-

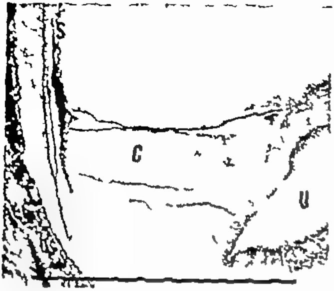

Fig 7 Left ear from 6 month bilaterally deaf white cat showing saccule (*S*), utricle (*U*) and the "cyst" formation (*C*) in the postero-superior corner of the saccular lumen Marker = 1 mm.

or juxta utricular pole of the saccule Commencing degeneration of the supporting cells is evident and in some areas towards the anterior pole, the layer of supporting cells is patchily absent The uniform layer of eosinophilic precipitate found in the previous age group is now broken up into localised accumulations of a more deeply eosinophilic material A definite layer is found only at the posterior pole where sensory cells can still be identified

At twenty-one months further reduction in sensory cell numbers has occurred and there is little eosinophilic precipitate remaining. A very few sensory cells remain at the postero-superior corner of the macula In the eight year-old adult (Fig 6 F) the layer of deeply basophilic staining otoconia persists, apparently unchanged and remains enclosed in the cellular membrane No sensory cells can be identified and the supporting cells are markedly degenerated, the cell borders cannot be identified and the nuclei are pyknotic There are many areas especially towards the anterior pole where also the supporting cells are absent

Both the obliteration of the saccular lumen and the subsequent degeneration of the macula first of the sensory cells and at a later stage, of the supporting cells, commence at the anterior or cochlear pole of the saccule and extend successively in a posterior direction. The posterior or juxta utricular part of the saccular lumen is, however never obliterated A constant feature which first makes its appearance at day twenty and thereafter persists throughout life is the appearance of a cyst like formation in the postero-superior corner of the saccular lumen. A typical "cyst" from a six month deaf cat is shown in Fig 7 None of the hearing ears presented this finding Study of consecutive sections has shown that the "cyst" is formed by a herniation medially and superiorly of the lateral saccular wall into the patent postero-superior corner of the saccular lumen The structure is therefore cone-shaped and communicates laterally and inferiorly with the perilymphatic space of the vestibule Considerable variation in size was found the largest having a vertical height of 220 microns and the smallest about 60 microns. The size of the "cyst" was not related to the age of the animal None of the specimens showed defects in the "cyst" wall which would permit admixture of perilymph and endolymph, and no adhesions were found between the "cyst" walls and the inner aspect of the saccule

The utriculosaccular duct and the ductus endolymphaticus were patent in all pathological ears. The endolymphatic sac contained a variable amount of deeply eosinophilic staining material, but the picture was inconstant. A ten month animal with unilateral degeneration showed considerable precipitate, especially in the rugose portion of the sac, but the amount and the staining characteristics were similar in both ears. In the deaf adult animals the amount of precipitate varied from slight through moderate to considerable No otoconia were found in the endolymphatic duct or sac and there were no significant differences in the dimensions of the vestibular aqueduct and endolymphatic ducts of pathological and normal ears The lumen of the ductus reuniens was markedly reduced and often obliterated in the older pathological ears.

No differences were found in the amount or distribution of pigment in the vestibular labyrinth in the three groups studied for this pur

encapsulation. It is tempting to regard this encapsulation as a protective response of the organism to injury. Deol & Lane (1966) have presented evidence which would suggest that the otoliths are secreted by the maculae. If this hypothesis is correct, the presence of an histologically normal otolithic layer at the eight day stage would indicate that at least part of the macula has been capable of normal function prior to that date.

The waltzer-shaker group of mouse mutants has been classified into two groups on the basis of differences in the time course of the labyrinthine degeneration (Grüneberg, 1955). In the morphogenetic group the labyrinth shows gross structural abnormalities which must have occurred at an early stage of embryogenesis. The development of the labyrinth in the second, degenerative, group proceeds normally up to, and for a variable time interval subsequent to, birth before degeneration occurs. Ormerod (1960) considered that the Scheibe type of abnormality represented a degenerative effect, but Deol (1968) disagreed with this view. The light microscopical evidence from the white cat favours the former hypothesis, but it is probable that electron microscopy would reveal structural changes at an even earlier date (Ernstson et al., 1969).

The acoustic ganglion has been shown to arise, at least in part, from the neural crest (Deol, 1967) and inner ear abnormalities have been regarded as an expression of genetically determined abnormalities in the latter structure. The finding of cells morphologically similar to Scarpa ganglion cells in the saccular macula may be indicative of anomalous innervation of the end-organ at an early stage in development. The absence of ganglion cell loss in the saccular division of Scarpa's ganglion is in marked contrast to the situation found in the spiral ganglion of the deaf white cat (Mair IV).

In the mouse a high degree of correlation has been found between the extent of hereditary inner ear degeneration and the distribution of pigment in the labyrinth (Deol, 1970). In addition, the two ears of individual animals often showed asymmetrical degeneration of both the cochlea and the saccule. The situation in the white cat would appear to be completely different. In animals with bilateral hearing loss the saccular degeneration was symmetrical at all stages, and no correlation could be found between the presence of cochleo-saccular degeneration and the amount or distribution of pigment in the membranous vestibular labyrinth. Bilateral symmetry also characterises the cochlear (Mair III) and the spiral ganglion (Mair IV) degenerations in the bilaterally deaf white cat.

ZUSAMMENFASSUNG

Eine elektronystagmographische Untersuchung der Vestibularfunktion bei tauben weissen Katzen ergab keine funktionellen Anomalitäten. Histologische Veränderungen wurden im Sacculus nachgewiesen und waren als Funktion des zunehmenden Alters stärker ausgeprägt. Einem Kollaps der Sacculus-Wand folgte ein Einkapselung der otolithischen Membran. In allen Stadien der degenerativen Prozesses war der Kochlea am nächsten liegende Abschnitt des Sacculus stärker betroffen als die weiter dorsal gelegenen Bereiche. Die degenerativen Veränderungen dehnen sich strahlenförmig vom Ductus reuniens aus und zeigen keine Korrelation zum Ausmass der Innenohr Pigmentierung.

Ernstson, S., Lundquist, P.-G., Wedenberg, E. & Wersäll, J. 1969. Morphologic changes in vestibular hair

gressively greater in the more posterior parts of the saccule This contrasts with the report of more severe hair cell degeneration in the posterior part of the macula sacculi in three species of dog with hereditary cochleo-saccular degeneration (Igarashi et al 1972) Cochlear degeneration in the deaf white cat is also characterised by unequal rates of degeneration the basal coil being affected first and the apical last (Mair III) Cochleo-saccular degeneration in the deaf white cat would therefore appear to develop centrifugally from the region of the ductus reuniens

The important stages of the inner ear degeneration in the deaf white cat have been previously reported to be virtually complete by the twenty first day (Bosher & Hallpike 1965) The present study confirms that the volume changes in the saccule with near obliteration of the lumen, are fully advanced by day twenty but significant sensory cell loss does not occur until later between day twenty six and day forty three and loss of supporting cells is not evident until after six months The degenerative process is a continuous one and apparently persists throughout life there being a marked difference in the extent of macular cell loss between the four year and the eight year deaf adult animals. In contrast to previous reports (Wilson & Kane 1959 Suga & Hattler 1970) a normal saccule was never found in deaf ears.

The finding of a normal pars superior in the presence of almost complete obliteration of the cochlear and saccular endolymphatic spaces supports the contention of Schuhneckt & McNeil (1966) that the sources of endolymph production are independent in the phylogenetically different parts of the labyrinth Obliteration of the saccular lumen is however not complete the posterior part remaining patent in all cases a finding which has been previously noted by Bosher & Hallpike (1965) There are however no other reports in the literature of the peculiar infolding of the postero-lateral saccular wall which produced the "cyst" formation found in all the pathological ears The significance of this finding is at present unclear but the infolding was definitely not produced by adhesions and may therefore be an expression of unequal pressure gradients on the opposing sides of the saccular wall Perlman (1940) described a reenforced area in the anterior part of the lateral saccular wall in the human labyrinth and demonstrated that the more posterior areas were more susceptible to pressure changes. However since this reenforcement was not present in lower animals, including the cat, the explanation of the "cyst" formation must be sought elsewhere

Defects in the saccular wall, similar to those described in the deaf Hedlund white mink (Sugiura & Hilding, 1970) were not found Rupture of the saccular wall with admixture of perilymph and endolymph is therefore not an aetiological factor in the development of the degenerative process in the deaf white cat. The utriculo-endolymphatic valve was intact in all specimens and it is therefore possible that the fluid presumably endolymph, present in the patent posterior part of the saccule was derived from the endolymphatic duct or sac (Seymour 1960).

Envelopment of the retracted tectorial membrane by a layer of flattened cells has been frequently reported in studies of human and animal deafness (Ward et al 1962 Suga & Hattler 1970) but reports of a similar process in the saccule are rare Myers et al (1971) found the saccular otolithic membrane completely encased in a fibrous tissue envelope in the temporal bones of a seven day old boy with the syndrome of deafness spiny hyperkeratosis and universal alopecia. A similar process has also been reported in measles virus labyrinthitis (Lindsay & Hemenway 1954) No other reports were found in the literature

In this series of deaf white cats the saccular otoliths were first surrounded by a layer of flattened cells at the twelve day stage, and this cellular response increased as a function of age Little change occurred in the otoconia between twenty days and eight years of age Quantitative increase of the saccular otoliths with subsequent fragmentation and scattering of the layer have been described in the mouse (Deol 1970) whereas the response in the cat is confined to an early increase in size of the individual otoconia with

III Cochlear Histopathology

Abstract The degeneration process in the cochlea of the hereditarily deaf white cat was studied in different age groups and the early stages compared with the postnatal morphological maturation in the hearing animal. Both processes commence in the upper half of the basal coil and extend longitudinally along the duct. Obliteration of the cochlear duct and degeneration of the stria vascularis are prominent early features, but no hydrops was found A radial progression across the basilar membrane also occurs, the outer hair cells degenerating before the inner A conspicuous feature, which is first found in the twelve day deaf animal, is the appearance of discrete, homogeneous spheres in the tectorial membrane. These structures appear to emanate from the region of the interdental cells

Deafness which is present at or soon after birth may have either an acquired or a hereditary aetiology The histopathological findings in human congenital deafness have been reviewed by Ormerod (1960) and classified into two major groups those cases in which there is a serious under or maldevelopment of the inner ear and a second group in which degenerative changes occur in the end organ at a later stage of development.

The most frequent temporal bone finding in the former developmental or morphogenetic group, is the Mondini type of aplasia with, *inter alia*, anomalies of the osseous labyrinth framework (Altmann, 1950 Beal et al 1967). A developmental aetiology can often be assumed in those ears in which malformations of the membraneous labyrinth are associated either with abnormalities of the bony labyrinth or with atresia of the external meatus (Altmann, 1950). Further differential diagnostic information is provided by the presence of associated anomalies as in the Arnold–Chiari malformation (Altmann, 1964) and the trisomy syndromes (Kos et al 1966). However developmental disorders at an early stage in embryogenesis are not necessarily synonymous with a hereditary aetiology

The situation with respect to the second group of degenerative or regressive changes in the labyrinth is even more uncertain Here, the Scheibe or cochleo-saccular type of degeneration is the most common (Altmann 1950 Ormerod, 1960), but similar temporal bone findings have been reported in hereditary deafness (Fisch, 1959), in deafness due to viral infection (Lindsay & Hemenway 1954) and in presbycusis (Schuknecht et al., 1965) in human material The difficulties in deciding whether deafness in the individual case is hereditary or acquired are often insurmountable (Beal et al. 1967 Lindsay & Matz, 1968)

Human studies are hampered by the comparative dearth of histological material and by the impossibility of genetically controlled investigations. These factors do not apply to animal studies and, fortunately many species present hereditary disorders of the labyrinth, some of which are histologically similar to presumed hereditary deafness in man. Particular attention has been paid to the hereditary inner ear degeneration of the various mouse mutants in the waltzer–shaker group These mutants have also been classified into a morphogenetic group, in which gross abnormalities of the labyrinth arise at an early stage in development, and a degenerative group, where the gross structure of the labyrinth is normal at birth, but degenerative changes appear in the neuroepithelia at a variable period thereafter and are usually progressive (Grüneberg, 1955). The cochleae of these latter mutants present to a varying degree a degeneration of the organ of Corti, the stria vascularis and the spiral ganglion. In several mutants the cochlear changes are accompanied by a progressive degeneration of the saccular macula (Deol, 1968), i.e. Scheibe type, whereas in others

III Cochlear Histopathology

Abstract The degeneration process in the cochlea of the hereditarily deaf white cat was studied in different age groups and the early stages compared with the postnatal morphological maturation in the hearing animal. Both processes commence in the upper half of the basal coil and extend longitudinally along the duct. Obliteration of the cochlear duct and degeneration of the stria vascularis are prominent early features, but no hydrops was found. A radial progression across the basilar membrane also occurs, the outer hair cells degenerating before the inner. A conspicuous feature, which is first found in the twelve day deaf animal, is the appearance of discrete, homogeneous spheres in the tectorial membrane. These structures appear to emanate from the region of the interdental cells

Deafness which is present at or soon after birth may have either an acquired or a hereditary aetiology. The histopathological findings in human congenital deafness have been reviewed by Ormerod (1960) and classified into two major groups: those cases in which there is a serious under- or maldevelopment of the inner ear, and a second group in which degenerative changes occur in the end organ at a later stage of development.

The most frequent temporal bone finding in the former developmental or morphogenetic group is the Mondini type of aplasia with, *inter alia*, anomalies of the osseous labyrinth framework (Altmann, 1950; Beal et al., 1967). A developmental aetiology can *often* be assumed in those ears in which malformations of the membraneous labyrinth are associated either with abnormalities of the bony labyrinth or with atresia of the external meatus (Altmann, 1950). Further differential diagnostic information is provided by the presence of associated anomalies as in the Arnold-Chiari malformation (Altmann, 1964) and the trisomy syndromes (Kos et al., 1966). However developmental disorders at an early stage in embryogenesis are not necessarily synonymous with a hereditary aetiology.

The situation with respect to the second group of *degenerative or regressive* changes in the labyrinth is even more uncertain. Here, the Scheibe, or cochleo-saccular type of degeneration is the most common (Altmann, 1950; Ormerod, 1960) but similar temporal bone findings have been reported in hereditary deafness (Fisch, 1959), in deafness due to viral infection (Lindsay & Hemenway, 1954) and in presbycusis (Schuknecht et al., 1965) in human material. The difficulties in deciding whether deafness in the individual case is hereditary or acquired are often insurmountable (Beal et al., 1967; Lindsay & Matz, 1968).

Human studies are hampered by the comparative dearth of histological material and by the impossibility of genetically controlled investigations. These factors do not apply to animal studies and, fortunately, many species present hereditary disorders of the labyrinth, some of which are histologically similar to presumed hereditary deafness in man. Particular attention has been paid to the hereditary inner ear degeneration of the various mouse mutants in the waltzer–shaker group. These mutants have also been classified into a morphogenetic group, in which gross abnormalities of the labyrinth arise at an early stage in development, and a degenerative group, where the gross structure of the labyrinth is normal at birth, but degenerative changes appear in the neuroepithelia at a variable period thereafter and are usually *progressive* (Grüneberg, 1955). The cochleae of these latter mutants present to a varying degree a degeneration of the organ of Corti, the stria vascularis and the spiral ganglion. In several mutants the cochlear changes are accompanied by a progressive degeneration of the saccular macula (Deol, 1968), i.e. Scheibe type, whereas in others

the sensory structures of the pars superior are affected to a varying degree (Deol 1954)

In 1910 van Lennep showed that the inner ear of the Japanese waltzing mouse was morphologically normal at birth and that the structural changes did not develop until ten days post partum, being thereafter progressive with age The time course of the inner ear degeneration has since been established for a great variety of mouse mutants (Deol 1968) Other species which have been extensively studied are the Hedlund white mink (Sugiura & Hilding, 1970) and the waltzing guinea pig (Ernstson 1971)

Although the literature on hereditary hearing loss contains many detailed descriptions of the time course of the cochlear degeneration in rodents, there are few comparable studies in the hereditarily deaf white cat Degeneration of the organ of Corti with collapse of the cochlear duct was first observed in the deaf white cat at the turn of the century (Rawitz, 1897 Alexander 1900) and this picture of the late stages of the degenerative process has since been confirmed by several investigators (Wilson & Kane, 1959 Suga & Hattler 1970) The different stages in the development of the cochlear end organ degeneration in the deaf white cat have been previously described only once in any detail in the literature (Bosher & Hallpike 1965) The current report presents the cochlear histopathological findings from a larger series of deaf animals studied over a longer survival period with emphasis on some important features which have not previously been described.

MATERIAL AND METHODS

A white cat stock of ninety-six animals was gradually acquired over a period of time Details of this population have been given previously (Mair I) Cochlear potential measurements from a round window electrode were performed bilaterally in all 96 animals and in a control group of 54 colour coat kittens and adult cats. The presence or absence of hearing was unequivocally established for all animals over seven days of age Bilateral hearing loss was found in 26 and unilateral in 8 of the white coat animals. All colour coat animals from the experimental stock and all 54 of the control group had cochlear potentials within the range of normal for the respective age groups Both the coloured and white coat populations were sacrified at varying intervals after birth by the standard method of intravital cardiac perfusion using Heidenhain s Susa solution as fixative Survival periods varied from the first postnatal day up to eight years of age The temporal bones and hind brains were removed in separate blocks in the majority of animals, and in all cases were processed for light microscopy The temporal bones were imbedded in celloidin with the mid modiolar axis of the cochlea orientated in the horizontal plane. Serial sections were cut at a thickness of 20 microns and every tenth and in many ears fifth section was stained with haematoxylin and eosin

The important early stages of the degenerative process in the deaf white cat were compared with the normal postnatal maturation of the cochlea in colour coat animals. A quantitative estimation of the latter was obtained by measurements of the organ of Corti in five selected age groups of kittens and hearing adult cats. Mid modiolar sections were studied and measurements made in the upper half of each coil using a micrometer eye piece attachment. The height of the open tunnel of Corti was measured as the perpendicular from the upper surface of the basilar membrane to the contact point of the pillars. Hair cell length was taken as the distance along the long axis from the base of the cell to the mid point of the diagonally inclined cuticular plate The greatest transverse diameter of the hair cell at the level of the nucleus was measured to represent the width. Measurements were not practicable in the hook region on account of the angle of section The postnatal development of the normal cochlear duct and of the degenerative process in the cochlea of the deaf white cat were studied in progressively older age groups and in all coils of the cochlea.

Table 10. *Tunnel of Corti, mean height in microns and standard deviation (n = 6) of open tunnel in different postnatal age groups of colour coat animals*

Age in days	Height Coil 1	Coil 2	Coil 3
1	13.4±10.45	0	0
5	27.1±2.47	0	0
8	33.5±3.50	34.5±6.37	0
10	38.4±2.37	44.5±3.68	39.0±5.43
30	39.5±1.68	44.8±1.79	42.9±2.37
Adult	40.4±1.02	45.0±1.58	45.1±1.67

RESULTS

1. *Postnatal development in normal colour coat stock*

The postnatal morphological maturation of the organ of Corti in colour coat stock was found to commence in the upper half of the basal coil and to extend longitudinally along the cochlear duct from this site. The dimensions of the open tunnel of Corti and of the inner and outer hair cells of colour coat animals are shown in Tables 10–12 for five age groups of kittens, aged from one to thirty days, and for adult animals. Opening of the tunnel and histological maturation of the outer hair cells occurred at approximately the tenth day in the hook region, but the angle of section did not permit a more accurate assessment. Table 10 demonstrates that the tunnel is patent only in coil one at the fifth day opens first in coil two at day eight and at the apex by the tenth postnatal day. The dimensions of the inner hair cells do not change significantly from the first postnatal day to the adult stage in any of the coils (Table 11). On the other hand, maturation results in a striking change in the configuration of the external hair cells (Table 12). In the newborn these cells are short and wide, whereas in the mature cochlea they are long and slender. This process parallels the opening of Corti's tunnel. Thinning and elongation of the outer hair cells have occurred by day five in the first coil, by day eight in coil two and by the tenth day in the apical coil.

2. *Pathological material*

No abnormalities were found in the osseous cochlear framework in the sixty deaf ears from the white cat stock. Pathological changes were confined to the structures of the membranous cochlear duct and the spiral ganglion. The latter will be described in a succeeding publication. The first light microscopical sign of a departure from the normal course of postnatal maturation was found at day eight, and consisted of a wavy appearance of Reissner's membrane in the upper half of coil one. Two days later, at day ten, Reissner's membrane is in contact with the inner limbal zone of the tectorial membrane in the first coil (Fig. 9 Medea). At this stage the light microscopical appearances of Corti's organ in hearing and deaf animals are almost indistinguishable (Fig. 9 Kit 18 & Medea). At day twelve the dimensions of the cochlear duct are further reduced and Reissner's membrane *is now* in contact with the spiral prominence although the lumen is still patent above and below the

prominence and above Corti's organ (Fig. 9 Astyanax) Further development consists of an increasingly greater reduction of the cochlear lumen, with finally adhesion between Reissner's membrane on the one hand and the stria vascularis and degenerated Corti's organ on the other (Fig. 9 Romeo) These changes commence in the upper half of the basal coil and extend longitudinally along the cochlear duct from basal to apical coils and also towards the round window there being a time delay of approximately one to two days between coils one and two and a similar interval between the second and the apical coils. This regular sequential progression is a constant feature of the degenerative process for all structures of the cochlear duct, although the time intervals vary considerably

The cochlear duct volume was reduced in all ears with absent round window potentials In none of the deaf ears was a hydrops found

The degeneration process commences almost simultaneously in the pillars and hair cells, but the first signs are not visible until after Reissner's membrane has commenced to descend towards the stria and the basilar membrane These structural changes are first found in coil one, appear consecutively later in the upper coils and the hook region, and consist of a collapse of the rods hair cells and supporting cells towards the modiolus with subsequent degeneration of all cellular components of Corti's organ.

At day ten the rods of Corti are erect and the tunnel patent in the basal coil (Fig. 10 Medea) At the twelth day the pillars have collapsed towards the modiolus (Fig. 10 Astyanax). This process proceeds rapidly and one week later there is very little tunnel lumen visible in the second coil whereas in coil three the tunnel is still patent and the pillar cells erect Pillar cells can be identified in coil one at day fifty-three (Fig 10 Upsilon) but by six months have degenerated completely (Fig. 10 Andromache). At fourteen months no tunnel lumen can be identified in any coil and only the inner pillar cells are distinguishable in coils two and three During the second year the inner pillars are still present,

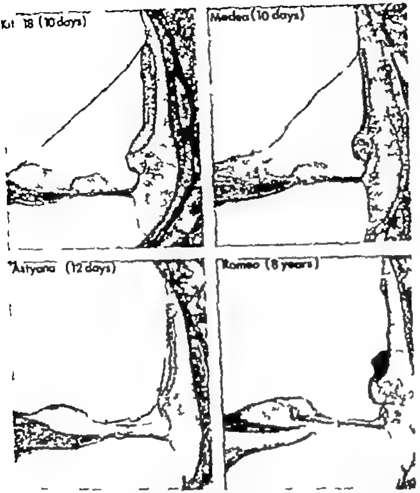

Fig. 9. Sections of the cochlear duct from the upper half of the basal coils. Kit 18: histologically mature Corti's organ from a ten day colour coat kitten. Medea: ten day deaf white cat. Reissner's membrane has an irregular wavy appearance and the stria vascularis is thinner than in the hearing animal. Astyanax: twelve day deaf white cat showing marked reduction of the endolymphatic space and collapse of Corti's organ. Romeo: eight year deaf white cat. There is total disappearance of Corti's organ, atrophy of the stria and considerable precipitate accumulation above the spiral prominence.

although deformed, in coil three, but after two years of age no pillars can be recognised in any coil.

A similar process is found in the hair cells, both inner and outer. Prior to the tenth day the cochlear development in the deaf white cat consists of a gradual histological maturation similar to that found in hearing animals. The tunnel opens, the outer hair cells lose their foetal appearance, become longer and thinner, and the extracellular spaces appear. At day ten the cytoplasm of the hair cells presents a granular appearance (Fig. 10, Medea). From day twelve onwards the hair cells accompany the pillars and collapse towards the modiolus (Fig. 10, Astyanax), first in coil one and subsequently in the upper coils. In the outer hair cells degeneration of the third row always occurs before rows one and two. Degeneration of the inner hair cells occurs at a somewhat later date than in the outer in all coils, and this interval is on the average two to four months. At day twenty the cell outlines of the outer hair cells in coil one can be identified only with difficulty and at day fifty-three all

prominence and above Corti's organ (Fig. 9 Astyanax). Further development consists of an increasingly greater reduction of the cochlear lumen, with finally adhesion between Reissner's membrane on the one hand and the stria vascularis and degenerated Corti's organ on the other (Fig. 9 Romeo). These changes commence in the upper half of the basal coil and extend longitudinally along the cochlear duct from basal to apical coils and also towards the round window, there being a time delay of approximately one to two days between coils one and two and a similar interval between the second and the apical coils. This regular sequential progression is a constant feature of the degenerative process for all structures of the cochlear duct, although the time intervals vary considerably.

The cochlear duct volume was reduced in all ears with absent round window potentials. In none of the deaf ears was a hydrops found.

The degeneration process commences almost simultaneously in the pillars and hair cells, but the first signs are not visible until after Reissner's membrane has commenced to descend towards the stria and the basilar membrane. These structural changes are first found in coil one, appear consecutively later in the upper coils and the hook region, and consist of a collapse of the rods, hair cells and supporting cells towards the modiolus with subsequent degeneration of all cellular components of Corti's organ.

At day ten the rods of Corti are erect and the tunnel patent in the basal coil (Fig. 10 Medea). At the twelth day the pillars have collapsed towards the modiolus (Fig. 10 Astyanax). This process proceeds rapidly and one week later there is very little tunnel lumen visible in the second coil, whereas in coil three the tunnel is still patent and the pillar cells erect. Pillar cells can be identified in coil one at day fifty three (Fig. 10 Upsilon), but by six months have degenerated completely (Fig. 10, Andromache). At fourteen months no tunnel lumen can be identified in any coil and only the inner pillar cells are distinguishable in coils two and three. During the second year the inner pillars are still present,

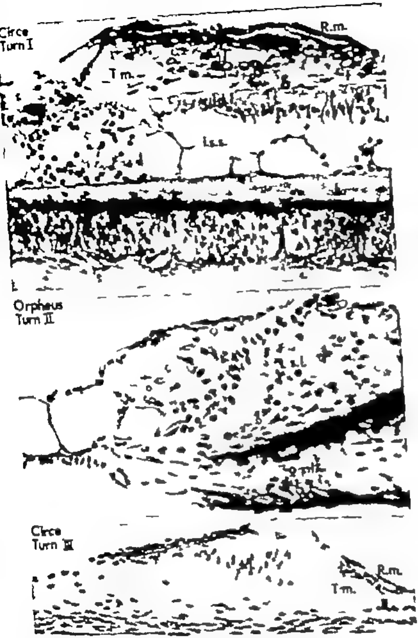

Fig. 11. Sections showing the varying appearance of the tectorial membrane and the blue-grey spheres in deaf animals. Abbreviations: T. m. Tectorial membrane; R. m. Reissner' membrane; l. spiral limbus; l. l. vestibular lip of the spiral limbus; o.s.l. osseous spiral lamina; inner spiral sulcus. Upper: basal half of coil one from 28 month deaf animal. A prominent feature of the vestibular lip is the row of Huschke's teeth with the interdental furrow containing the nuclei of the interdental cells. The tectorial membrane is covered on its upper surface by Reissner' membrane. Scattered throughout the former are numerous, spherical or elongated structures (arrows) which have an homogeneous appearance. Middle: second coil of 14 month deaf animal. The tectorial membrane is rolled up in the inner spiral sulcus and the spheres are prominent in the membrane and can also be traced along the upper surface of the vestibular lip. Lower: third coil of 28 month animal. No spheres are visible in this section of the tectorial membrane, but numerous elongated structures with the same staining characteristics are present on the upper surface of the vestibular lip (arrow).

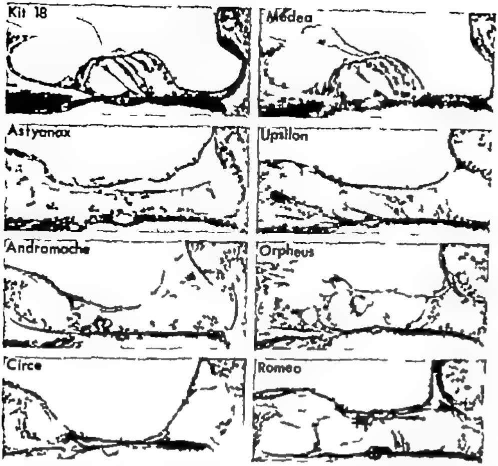

Fig 10 Higher power views of Corti s organ from the upper half of the basal coils. Kit 18 mature Corti's organ from ten day colour coat kitten. Medea, ten day deaf animal. Reissner s membrane has commenced to descend towards the tectorial membrane and the external hair and Deiter's cells have a granular appearance of the cytoplasm. Corti s tunnel is patent and the upper tunnel radial fibres are visible. Astyanax twelve day deaf animal. Reissner's membrane is in contact with the spiral prominence and covers the still elongated tectorial membrane. The pillar cells, hair and supporting cells have collapsed towards the modiolus, and large cystic spaces are found in the external sulcus cells. The vessel of the basilar membrane is large and patent. Upsilon fifty three day deaf animal. The tectorial membrane has retracted into the inner spiral sulcus and the pillar cells can be identified although deformed. The hair cells are degenerated and the cystic spaces in the outer sulcus cells have coalesced. Andromache six month deaf animal. The pillar cells are no longer identifiable and Corti s organ is replaced by undifferentiated cells. Further stages of this process are shown in the fourteen month (Orpheus), the twenty-eight month (Circe) and the eight year old adult (Romeo)

outer hair cell outlines are obliterated in this coil (Fig. 10 Upsilon) At this stage the first row of outer hair cells in coil two and all three rows in coil three are still distinguishable. Both inner and outer hair cells can be identified in the hook region at day fifty three Inner hair cells are first consistently absent in coil one at the ten month stage Increasing hair cell loss occurs in the first and second years (Fig 10 Andromache & Orpheus) and at twenty-two months no outer hair cells can be recognised although the inner hair cells are still present at the apex and towards the round window At twenty-eight months no inner hair cells can be identified throughout the cochlear duct. Hair cells are entirely absent in the adult.

The cells of Deiters and Hensen accompany the pillars and hair cells when the latter collapse towards the modiolus and can still be identified up to the end of the second month in the upper coils but thereafter further degeneration occurs No basal migration of the Deiters cell nuclei was observed The end result is a complete loss of cellular identity with either disappearance of Corti s organ, in which case Reissner s membrane lies in contact with the denuded basilar

coils and becomes covered with a monocellular sheath The blue-grey spheres are a constant feature in all deaf ears after day twelve They increase in size and number with age in the first two coils, but in coil three they remain small although becoming more numerous in the older age groups (Fig 11) The spheres are sparse in the hook region, but persist throughout the tectoral membrane apparently unchanged, even in the eight year deaf adult. Discrete, elongated structures, with staining characteristics similar to the spheres, can be traced along the vestibular lip between the spiral limbus and the tectorial membrane towards the region of the interdental cells (Fig 11) None of the hearing ears presented this finding.

The stria vascularis of the deaf white cat is indistinguishable at day eight from that of the hearing animal (Fig 12 A) At this stage the stria is well developed, especially the deep reticulated layer has an irregular surface in all coils and contains many capillaries. At day ten the surface of the stria in coil one is smoothed out (Fig 12 B) and the stria appears thinner than in the ten day hearing animal (Fig. 12 A) Two days later this surface change has extended to coil two and the spiral prominence of the first coil is now paler where Reissner s membrane is in contact (Fig 12 C) The stria subsequently becomes thinner and there is a progressive obliteration of the vascular spaces (Fig. 12 D–H). In the adult this process has progressed until the combined Reissner s membrane and stria are only one cell thick at the upper peripheral angle of the duct (Fig 12 H) Above the spiral prominence there appears in some sections a deeply eosinophilic staining precipitate which increases in quantity with age

The external sulcus cells appear unremarkable in the ten day deaf animal (Fig 10 Medea). Two days later these cells have increased greatly in size and the cytoplasm is paler and vacuolar with formation of large cystic spaces (Fig. 10, Astyanax) By day twenty the cystic spaces have increased further in size in all coils, and the nuclei appear pale with an irregular outline With increasing age the nuclei become more pyknotic (Fig. 10, Upsilon), the cystic spaces smaller and precipitate accumulates, eosinophilic beneath the spiral prominence and basophilic in the angle between the basilar membrane and spiral ligament. The latter presents an increasing pallor due to cell loss with advancing age, but no change is apparent in the basilar membrane Degeneration with ultimate disappearance is also found in the inner sulcus cells, but without the formation of cystic spaces (Fig. 10).

The vessel of the basilar membrane (vas spirale) is present in all age groups, although considerably larger in the younger animals (Fig. 10) In many sections this vessel gives the appearance of being occluded by an amorphous, lightly basophilic staining material, but in the oldest, eight ear deaf animal erythrocytes were visible in the vessel lumen in the basal coil (Fig. 10, Romeo) The cochlear vascular system was otherwise unremarkable.

The inner ear degeneration was strikingly symmetrical in both ears of bilaterally deaf animals irrespective of age The end result of this process of degeneration of the cochlear structures in the aged adult is shown in Fig 9 Romeo with obliteration of the endolymphatic space, complete disappearance of all components of Corti s organ and degeneration of the stria vascularis

DISCUSSION

Numerous morphological and physiological studies have shown that the cochlea of the newborn mammal is immature in many species, and that a rapid and systematic development occurs in the early postnatal period. The majority of investigators have demonstrated that the maturation process spreads sequentially along the cochlear duct from basal to apical coil (Deol, 1954 Ånggård, 1965). The present study of the colour coat stock confirms that histological maturation of the cat cochlea comences in the upper half of the basal coil and extends longitudinally along the cochlear duct, both apically towards the helicotrema and basally towards the round window The reported tunnel and hair cell meas

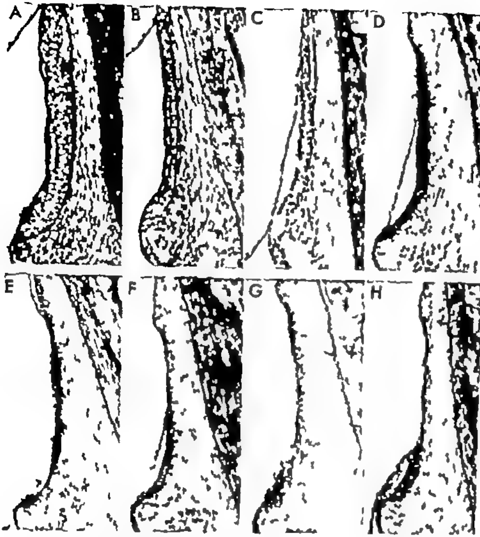

Fig 12 The stria vascularis, spiral prominence and spiral ligament from the upper half of the basal coil in different age groups. (A) 10 day hearing animal (B) 10 day deaf white cat. The stria is thinner than in A and the surface has a smoother appearance. (C) 12 day deaf animal. Reissner's membrane is in contact with the upper part of the stria and the spiral prominence. The latter appears paler but the stria still contains numerous vascular spaces. (D) 53 day deaf animal. The stria is more deeply staining, *cell outlines are largely obliterated and the vascular spaces* reduced considerably in diameter (E) 6 month deaf animal The degenerated stria and Reissner's membrane have coalesced There is marked cell loss in the stria and absence of vascular spaces. membrane (Fig. 10, Circe) or else persistence of some degenerated cells with fibrous adhesions between the two membranes (Fig 10 Romeo) *Both of these end stages can usually be found* at different sites in the same ear

The tectorial membrane at day ten is in its limbal zone in contact with Reissner's membrane due to the descent of the latter towards the basilar membrane Two days later almost the entire upper surface of the tectorial membrane is covered by the closely applied Reissner's membrane (Fig 10 Astyanax) The former is, however still elongated and in contact with Corti's organ Small, grey blue spheres are visible at day twelve along the undersurface of the tectorial membrane in coil one, and to a lesser extent in coil two One week later the tectorial membrane has retracted towards the inner sulcus and presents a rolled up globular appearance in the first coil This appearance is less marked in coil two and at the apex the membrane is still elongated and covering the persisting Corti's organ The membrane subsequently retracts towards the modiolus in all

coils and becomes covered with a monocellular sheath. The blue-grey spheres are a constant feature of all deaf ears after day twelve. They increase in size and number with age in the first two coils, but in coil three they remain small although becoming more numerous in the older age groups (Fig. 11). The spheres are sparse in the hook region, but persist throughout the tectorial membrane apparently unchanged, even in the eight year deaf adult. Discrete elongated structures, with staining characteristics similar to the spheres, can be traced along the vestibular lip between the spiral limbus and the tectorial membrane towards the region of the interdental cells (Fig. 11). None of the hearing ears presented this finding.

The stria vascularis of the deaf white cat is indistinguishable at day eight from that of the hearing animal (Fig. 12 A). At this stage the stria is well developed, especially the deep reticulated layer, has an irregular surface in all coils and contains many capillaries. At day ten the surface of the stria in coil one is smoothed out (Fig. 12 B) and the stria appears thinner than in the ten day hearing animal (Fig. 12 A). Two days later this surface change has extended to coil two and the spiral prominence of the first coil is now paler where Reissner's membrane is in contact (Fig. 12 C). The stria subsequently becomes thinner and there is a progressive obliteration of the vascular spaces (Fig. 12 D–H). In the adult this process has progressed until the combined Reissner's membrane and stria are only one cell thick at the upper peripheral angle of the duct (Fig. 12 H). Above the spiral prominence there appears in some sections a deeply eosinophilic staining precipitate which increases in quantity with age.

The external sulcus cells appear unremarkable in the ten day deaf animal (Fig. 10, Medea). Two days later these cells have increased greatly in size and the cytoplasm is paler and vacuolar with formation of large cystic spaces (Fig. 10 Astyanax). By day twenty the cystic spaces have increased further in size in all coils, and the nuclei appear pale with an irregular outline. With increasing age the nuclei become more pyknotic (Fig. 10 Upsilon), the cystic spaces smaller and precipitate accumulates, eosinophilic beneath the spiral prominence and basophilic in the angle between the basilar membrane and spiral ligament. The latter presents an increasing pallor due to cell loss with advancing age, but no change is apparent in the basilar membrane. Degeneration with ultimate disappearance is also found in the inner sulcus cells, but without the formation of cystic spaces (Fig. 10).

The vessel of the basilar membrane (vas spirale) is present in all age groups, although considerably larger in the younger animals (Fig. 10). In many sections this vessel gives the appearance of being occluded by an amorphous, lightly basophilic staining material, but in the oldest, eight year deaf animal erythrocytes were visible in the vessel lumen in the basal coil (Fig. 10, Romeo). The cochlear vascular system was otherwise unremarkable.

The inner ear degeneration was strikingly symmetrical in both ears of bilaterally deaf animals irrespective of age. The end result of this process of degeneration of the cochlear structures in the aged adult is shown in Fig. 9 Romeo with obliteration of the endolymphatic space, complete disappearance of all components of Corti's organ and degeneration of the stria vascularis.

DISCUSSION

Numerous morphological and physiological studies have shown that the cochlea of the newborn mammal is immature in many species, and that a rapid and systematic development occurs in the early postnatal period. The majority of investigators have demonstrated that the maturation process spreads sequentially along the cochlear duct from basal to apical coil (Deol 1954, Änggård, 1965). The present study of the colour coat stock confirms that histological maturation of the cat cochlea commences in the upper half of the basal coil and extends longitudinally along the cochlear duct, both apically towards the helicotrema and basally towards the round window. The reported tunnel and hair cell meas-

membrane (Fig. 10 Circe) or else persistence of some degenerated cells with fibrous adhesions between the two membranes (Fig. 10 Romeo) Both of these end stages can usually be found at different sites in the same ear

The tectorial membrane at day ten is, in its limbal zone, in contact with Reissner s membrane due to the descent of the latter towards the basilar membrane Two days later almost the entire upper surface of the tectorial membrane is covered by the closely applied Reissner s membrane (Fig 10 Astyanax) The former is however still elongated and in contact with Corti s organ. Small grey blue spheres are visible at day twelve along the undersurface of the tectorial membrane in coil one, and to a lesser extent in coil two One week later the tectorial membrane has retracted towards the inner sulcus and presents a rolled-up globular appearance in the first coil This appearance is less marked in coil two and at the apex the membrane is still elongated and covering the persisting Corti s organ The membrane subsequently retracts towards the modiolus in all

of hereditary degeneration in the youngest cells of the cochlea may be a manifestation of a similar difference in susceptibility. In this context it is perhaps noteworthy that the basal coil is also more susceptible to damage in ototoxicity (Benitez et al. 1962), in presbycusis (Schuknecht et al. 1965) and in viral labyrinthitis (Lindsay & Hemenway 1954).

Many theories as to the pathogenesis of the inner ear degeneration in the deaf white cat have centered around disorders of endolymph production (Wilson & Kane, 1959. Bosher & Hallpike, 1965). The latter authors stressed the importance of volume oscillations of the endolymph in the scala media with subsequent mechanical deformation of Corti's organ, adducing as evidence the finding of an hydrops in certain of their animals, and the folding of Reissner's membrane following its collapse towards the basilar membrane. A careful study of the sixty deaf ears in the present series, especially of the younger animals, failed to produce any evidence either of cochlear or of saccular hydrops. It may be significant that a cochlear hydrops of slight to moderate degree was found in three coloured coat kittens with normal round window potentials and otherwise unremarkable cochlear histology.

Sagging of Reissner's membrane is the earliest light microscopical abnormality in the cochleo-saccular degeneration of the deaf Hedlund white mink (Sugiura & Hilding, 1970), but electron microscopy has revealed an earlier absence of mitochondria in the strial marginal cells (Hilding et al. 1967). A similar process of a sudden and rapid reduction in endolymph volume in the cochlear duct and saccule of the deaf white cat is already visible at day eight. A reduction of endolymph, but apparently not an over-production, is thus an early feature of the degenerative process in the cat, but whether the strial atrophy is causally involved in the degeneration of Corti's organ is at present uncertain. Investigations in other species have shown that these two processes may occur independently. Grüneberg (1955) presented evidence which contradicted his own, earlier hypothesis that the organ of Corti degeneration in the mouse was secondary to strial changes. In the mouse mutant piebald-lethal, long stretches of histologically and functionally normal hair cells occur in the presence of obvious abnormality of the entire length of the stria (Deol, 1967). On the other hand complete degeneration of Corti's organ occurs in the presence of only scattered patches of very moderate strial atrophy in the waltzing guinea pig (Ernstson, 1971). The strial degeneration in the cat may therefore be a concomitant manifestation of an as yet unidentified developmental defect.

The vessel of the basilar membrane has been shown to be of prime importance for the nutrition of the hair cells (Lawrence 1966). Electron microscopy in shaker 1 mice has revealed involution and obliteration of this vessel (Kikuchi & Hilding, 1967). Absence has also been described in the deaf dalmatian dog (Anderson et al. 1968), although Igarashi et al. (1972) found this vessel to be patent in deaf dalmatian puppies. Although some degree of involution is normal in the adult cat it would appear that patency of the lumen is retained in the deaf adult animal.

It is possible that the external sulcus cells are involved in the nutrition of Corti's organ (Crowe et al., 1934). The marked hyperplasia of these cells in the deaf cat has been described previously (Bosher & Hallpike, 1965) but this development occurs after the first signs of degeneration in the organ of Corti. An explanation for this apparent over-activity is not at present possible.

Retraction of the tectorial membrane into the inner spiral sulcus with formation of a globular mass and encasement in a layer of flattened cells has been described in hereditary (Fisch, 1959) and acquired human deafness (Lindsay & Hemenway 1954) and in the hereditary deafness of animals (Suga & Hattler 1970), and is very similar to the process found in the saccular otolithic membrane of the deaf white cat (Mair II). No other reports of the peculiar sphere-like structures present in the tectorial membrane could be found in the literature. These spheres first make their appearance along the undersur-

urements are largely in agreement with those of Retzius (1884)

Several investigators have confirmed the absence of round window potentials in the deaf white cat but the literature contains few descriptions of the early stages of the degenerative process in the cochlea. The only other detailed investigation reported that no morphological abnormalities were present in the first four days of life that the important stages were well advanced by the twelth day and virtually complete by the twenty first (Bosher & Hallpike 1965) The longest survival time in that series was 281 days These authors apparently observed simultaneous degeneration in all coils and concluded that the process was a degeneration of a morphologically mature organ in the first coil but in the apical coil was a combination of degeneration and arrested development More recently Bergsma & Brown (1971) reported that the organ of Corti in the deaf white cat may be normal in some areas whilst affected in others, but their study was restricted to *young* animals

The present material conclusively demonstrates *that the early stages of the degenerative process* in the cochlea of the deaf white cat follow *a regular pattern which parallels the postnatal* maturation of the hearing cochlea, with sequential *changes which spread longitudinally along* the duct from the upper half of the basal coil It would appear that *the different coils of the* cochlear duct *must first reach a certain stage of* morphological maturation before the genetically determined degeneration process can commence (Anderson et al. 1968)

In addition to the longitudinal progression along the duct there is also a radial progression across the basilar membrane, the outer hair cells being affected before the inner and the outermost row of the former before the two inner rows. Hair cell degeneration occurs first in the third row of the outer hair cells in the upper basal coil whilst *the inner hair cells at* both extremities of the cochlear duct have the longest survival time A similar finding of a radial progression across the duct has been reported in the waltzing guinea pig (Ernstson, 1971) the Hedlund white mink (Sugiura & Hilding, 1970) and in the dalmatian dog (Johnsson & Hawkins, 1972) The latter authors reported that the external hair cells first showed signs of degeneration in the second week after birth whilst degeneration of the inner hair cells did not commence until some weeks later The degenerative process in the deaf dalmatian dog and the white cat is therefore strikingly similar

Once the process of degeneration commences around the beginning of the second week it progresses rapidly and all structures in the basal coil are severely affected by the end of week three The process is however not virtually complete by the twenty-first day as maintained by Bosher & Hallpike (1965) but is progressive throughout the animal s life span Inner hair cell loss, for example, *is minimal prior to the six to ten month* stage and an eight year old animal shows a much greater degree of end-organ degeneration than does a two year old adult Moreover degeneration of the spiral ganglion with neuronal loss is *not evident until towards the end of the first year* (Mair IV). A similar process of progressive *degeneration with increasing age has been earlier* described in the saccule of the deaf white cat *(Mair II) The hereditary cohleo-saccular de*generation in the white cat is an all-or-none *phenomenon and once the process commences* it will progress in a fixed and constant pattern from the zones of predilection to involve all the *sensory and supporting* cells of the cochlea and the saccule

The upper basal coil is also the most severely affected in the similar cochleo-saccular degeneration found in several species of dog, and Igarashi et al (1972) concluded that this area may be the most fragile part of the cochlear end organ although the reason for this was unknown A radioautographic study of the inner ear development of the mouse has shown that the oldest cells of Corti s organ are found at the apex and *the youngest in the* basal coil (Ruben 1967) It is widely accepted *that the phylogenetically* younger pars inferior of the labyrinth is more susceptible *to a variety of nocuous agents* than is the older pars superior *The earlier appearance*

face of the membrane in the twelve day deaf animal and are thereafter a constant feature of all pathological cochleae. The spheres could be traced along the vestibular lip to the area of the interdental cells, but despite intensive search no direct evidence of secretion of these structures by the latter could be found.

Autoradiographic studies have shown that the interdental cells secrete mucopolysaccharides, and several investigators have provided evidence that the interdental cells secrete a material into the tectorial membrane (Iurato 1962, Ishiyama et al. 1970). It is therefore possible that the spheres consist of a material which would normally be incorporated into the substance of the tectorial membrane. The abnormal accumulation of this material first noted at day twelve may indicate that metabolic processes in the tectorial membrane have already ceased prior to this stage, whereas the increase in size and numbers of the spheres with age may be due to a continued metabolic activity of the interdental cells.

The pattern of degeneration is in several respects very similar in the cochlea and the saccule. In bilateral cases the histopathological findings are strikingly symmetrical. In both the cochlea and the saccule there is a zone of predilection, where the degeneration process commences, and which remains the most severely affected area. Volume reduction of both structures commences simultaneously and is almost complete by day twelve. Hair cell loss is first evident around the fourth week and the last surviving hair cells are found at the end of the second year in those areas of the saccule and cochlea which are furthest removed from the sites of predilection. In contrast, the afferent nerves present markedly different findings. Neuronal loss does not occur in the saccular division of Scarpa's ganglion (Mair II), whereas a progressive age-related ganglion cell loss is found in the spiral ganglion of the cochlea (Mair IV).

In human acquired cochleo-saccular degeneration, Reissner's membrane has either been normally situated or only slightly depressed (Schuknecht et al. 1965, Hemenway et al. 1969). The obliteration of the cochlear duct and of the greater part of the saccular lumen at an early stage in the deaf white cat may have differential diagnostic significance for congenital deafness of the Scheibe type in humans. An additional important feature is the orderly and systematic progression which characterises this type of hereditary degeneration. Conclusions from this series will, however, remain purely speculative, and emphasises once again the need for further studies of human material.

ZUSAMMENFASSUNG

Es wurde der Ablauf der Degeneration in der Cochlea bei der erblich tauben weissen Katze in verschiedenen Altersklassen untersucht. Die frühen Degenerationsstadien wurden mit den Stadien der postnatalen morphologischen Reifung beim hörenden Tier verglichen. Beide Prozesse beginnen in der oberen Hälfte der basalen Windung und schreiten longitudinal entlang des Ductus fort.

Die Obliteration des Cochleaganges und die Degeneration der Stria vascularis sind die herausragenden frühen Geschehen; es wurde jedoch kein Hydrops beobachtet.

Es kommt auch zu einer radialen Ausbreitung durch die Basilarmembran hindurch; die äusseren Haarzellen degenerieren früher als die inneren. Bemerkenswert jedoch erst beim 12 Tage alten tauben Tier nachweisbar ist das Auftreten kleiner homogener Kügelchen in der Membrana tectoria; diese Strukturen scheinen aus dem Bereich der interdentalen Zellen zu stammen.

extent of spiral ganglion degeneration found in different temporal bones (Brown & Chung, 1971).

The present report contains the results of a quantitative study of the degeneration process in the spiral ganglion of the hereditarily deaf white cat.

MATERIAL AND METHODS

A white cat stock of 96 animals was accumulated over a period of time. Recordings of cochlear potentials from round window electrodes showed that 26 white coat animals were bilaterally and 8 unilaterally deaf. Both the hearing and the deaf animals were sacrificed at varying ages from the early postnatal period up to eight years of age by the standard method of intravital cardiac perfusion using Heidenhain's Susa solution as fixative. The temporal bones were processed for light microscopy and embedded in celloidin with the mid-modiolar axis of the cochlea orientated in the horizontal plane. Serial sections were cut at a thickness of 20 microns and every tenth, and in some cases every fifth, section stained with haematoxylin and eosin.

The development of the degeneration process was first studied in the end-organ, and the time course established for the principal constituents of the cochlear duct (Mair). The degeneration of the spiral ganglion was investigated and compared with the age of the animal and the degree of end-organ degeneration.

Graphic reconstructions of the organ of Corti and the spiral ganglion were performed in fourteen ears according to the technique of Guild (1921). The spiral ganglion was subdivided into six segments by the vertical line through the tangential sections as shown in Fig. 13. The lengths of the reconstructed spiral ganglions and the six segments were measured, corrected for magnification and the mean lengths and standard deviations calculated.

Spiral ganglion cell counts were performed in seventeen functionally and histologically normal ears of different age groups, and in forty-eight of the deaf ears. Counts of the remaining twelve deaf ears were not performed due to a variety

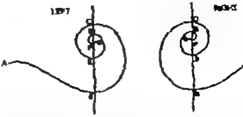

Fig. 13. Diagram of reconstructed spiral ganglion. The spiral ganglion, AO, is subdivided into six segments by the vertical line which joins the tangentially cut sections at B, C, D, E and F.

of technical imperfections in the histological processing. Ganglion cells were counted under high-dry magnification using an eyepiece-reticule, every tenth, and in some ears every fifth, section being studied. All ganglion cells which contained a definite nucleolus were counted, the focus being constantly varied from upper to lower surface of the sections. As every tenth section was counted a multiplication factor of 9.5 was used to calculate the total ganglion cell populations and simultaneously correct for the possibility of split nucleoli (Schuknecht, 1960). In those ears in which every fifth section was counted the average of the two measurements was taken and then multiplied by the same factor. In each ear the number of ganglion cells at the different levels of the cochlea were transferred to the appropriate points in the standard reconstruction graph described above, and the neuron densities per millimetre of the six subdivisions of the spiral ganglion calculated.

RESULTS

Reduction of the spiral ganglion cell population in Rosenthal's canal and degeneration of the cochlear nerve fibres in the modiolus were striking features of all adult, deaf ears. Approximately mid-modiolar sections from the right cochleae of four animals are shown in Fig. 14. The appearance of the adult cochlea with end-organ degeneration (Fig. 14, Romeo) is in marked contrast to that of the adult, hearing animal (Fig. 14, Achilles). Rosenthal's canal is

IV Primary Auditory Neuron Histopathology

Abstract The degeneration process in the spiral ganglion of the hereditarily deaf white cat was studied quantitatively in different age groups. Cochlear duct and spiral ganglion reconstructions were performed in hearing and pathological ears. The mean length of the spiral ganglion was 10 67 mm and the mean total neuron count from functionally and histologically normal ears was 51 770 Loss of spiral ganglion cells was first statistically evident after the ten month stage in deaf animals, and thereafter the spiral ganglion counts decreased progressively with age. The central portion of the ganglion showed the largest neuronal loss, there being relatively greater preservation at both extremities of Rosenthal's canal.

The topographical representation of the organ of Corti in the spiral ganglion is well established and it has been shown that a given unit length of the spiral ganglion innervates a longer segment of the cochlear duct at both extremities than in the middle coils (Sando 1965)

The degeneration behaviour of the bipolar cells in the spiral ganglion is markedly different from that of the histologically similar bipolar cells in the neighbourghing vestibular ganglion of Scarpa where direct trauma to the perikaryon is usually necessary to produce neuronal degeneration resulting in ganglion cell loss (Spoendlin, 1971) Experimental lesions of either the cochlear axons in the internal auditory meatus (Spoendlin & Gacek, 1963) or of the dendrites in the cochlear duct (Sando 1965), result in degeneration of the spiral ganglion cells Acoustic trauma (Lurie, Davis & Hawkins, 1944) blows to the head (Schuknecht, 1953) and ototoxicity (Hawkins, 1959) in experimental animals produce degeneration, first of the organ of Corti and subsequently of the afferent nerve fibres and the spiral ganglion cells. Degeneration of the afferent cochlear neurons occurs rapidly under these experimental conditions and ganglion cell loss is already evident after two to three weeks

In a review of inherited nerve deafness in man and animals, Altmann 1950 has subdivided the histological findings into a group with primary changes in the cochlear duct and saccule and a second category in which a primary degeneration of the spiral ganglion occurs. In the former group a degeneration of the afferent cochlear nerve fibres and of the spiral ganglion cells was not infrequently found and these changes were regarded as being probably secondary to those in the organ of Corti. Hereditary nerve deafness in association with disorders of pigmentation occurs both in man and in several species of animals The hearing loss of the Waardenburg syndrome in humans is associated with anomalies of hair iris and skin pigmentation and the sole temporal bone description in the literature mentions a marked loss of spiral ganglion cells and thinness of the cochlear nerve root in addition to a Scheibe type of cochleo-saccular end organ degeneration (Fisch, 1959)

Hereditary deafness in animals has been extensively studied in some species, and both in the waltzing guinea pig (Ernstson 1971) and several mice mutants (Deol 1970) it has been shown that spiral ganglion degeneration occurs at a variable interval after the degeneration of the end-organ In the hypopigmentation syndrome in the hereditarily deaf white cat a marked reduction in spiral ganglion neurons was already demonstrated in 1935 by Howe and several subsequent publications have confirmed this finding (Wilson & Kane, 1959 Bergsma & Brown, 1971) There are however neither long term nor quantitative studies of the spiral ganglion degeneration in the white cat and no precise information as to its time course although Howe (1935) did note that the greatest degree of neuronal degeneration was found in the oldest animals A recent publication on hereditary deafness has concluded that one of the problems requiring explanation is the variation in the

extent of spiral ganglion degeneration found in different temporal bones (Brown & Chung,1971).

The present report contains the results of a quantitative study of the degeneration process in the spiral ganglion of the hereditarily deaf white cat.

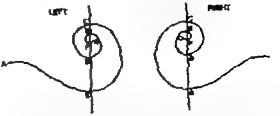

Fig. 13. Diagram of reconstructed spiral ganglion. The spiral ganglion, AG, is subdivided into six segments by the vertical line which joins the tangentially cut sections at B, C, D, E and F.

MATERIAL AND METHODS

A white cat stock of 96 animals was accumulated over a period of time. Recordings of cochlear potentials from round window electrodes showed that 26 white coat animals were bilaterally and 8 unilaterally deaf. A recent publication on hereditary deafness has concluded that one of the problems requiring explanation is the variation in the

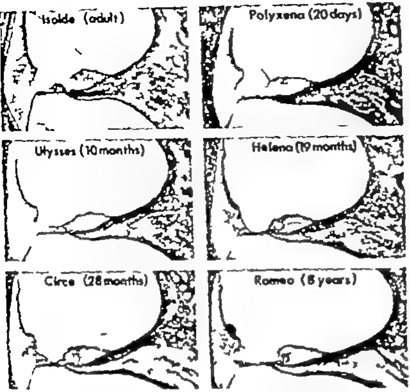

Fig. 15. Upper half of coil one showing the cochlear duct and Rosenthal's canal. Isolde, normal appearance of adult, hearing animal. Polyxena, 20 day deaf cat showing commencing degeneration of cochlear duct and normal density of ganglion cells. Ulysses, 10 month, deaf animal with marked end-organ degeneration and numerous ganglion cells in Rosenthal's canal. Helena, 19 month, deaf animal showing definite reduction in ganglion cell population. Greater degrees of ganglion cell loss are shown in the 28 month young adult (Circe) and in the 8 year adult (Romeo) animals.

ganglion cells show definite evidence of chromatolysis, whereas the majority of cells are indistinguishable from those of the hearing adult (Fig. 17, Isolde). A significant number of degenerating neurons first appears after the ten month stage. At nineteen months (Fig. 17, Helena) the majority of the surviving neurons have an unremarkable light microscopical appearance, but some degenerating ganglion cells are readily found. In the adult, many of the surviving neurons appear to be degenerating. The cells are considerably larger, have an eccentric, deeply-staining, irregular nucleus, the cytoplasm is more homogeneous, occasionally vacuolar, and Nissl granules are no longer evident (Fig. 17, Circe & Romeo).

Statistical confirmation for the theory of increasing neuronal degeneration as a function of age in the deaf animals was obtained by spiral ganglion reconstructions and ganglion cell counts. The lengths of the entire ganglion and the six subdivisions from fourteen reconstructed ears are presented in Table 13. The mean length of the spiral ganglion was 10.67 mm. In Table 14 are shown the total neuron counts and the neuron densities per mm of the six subdivisions of Rosenthal's canal in seventeen histologically and electrophysiologically normal ears. The mean total neuron count was found to be 51 770, with a range from 45 020 to 57 541. The total neuron counts in adult hearing cats are not significantly different from those found in young hearing animals, and the presence of degeneration in the contralateral ear has likewise no discernible influence in this series. The neuron densities per mm of the spiral ganglion are very

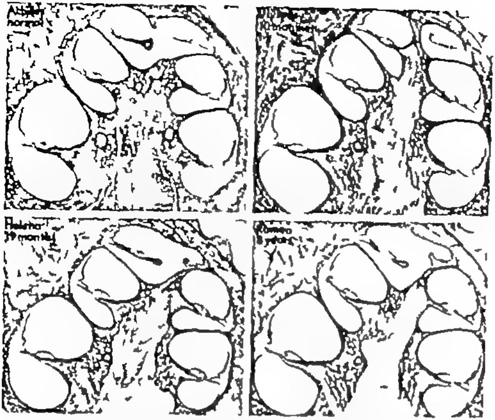

Fig 14 Approximately mid-modiolar sections of the right cochlea. Achilles adult, hearing animal showing normal appearance of cochlear duct, spiral ganglion and cochlear nerve. Ulysses. 10 month, deaf animal with degeneration of the cochlear duct. The cochlear nerve and spiral ganglion appear unremarkable. Helena 19 month, deaf animal with marked scala media degeneration and obvious ganglion cell loss in coils one and two and definite degeneration of the cochlear nerve. Romeo 8 year deaf animal with almost complete disappearance of cochlear nerve fibres and only a few ganglion cells in each coil

practically devoid of ganglion cells in the former and the cochlear nerve almost totally degenerated Progressively lesser degrees of ganglion cell loss and nerve degeneration are seen in the nineteen month (Fig. 14 Helena) and the ten month (Fig. 14 Ulysses) deaf ears. Indeed in the latter the appearance of the ganglion is little different from that found in the hearing adult (Fig. 14 Achilles) although the degeneration of the end organ is already well advanced at that age

The cochlear duct and the corresponding segment of the spiral ganglion from the upper half of the basal coil of six animals are shown in higher magnification in Fig. 15 The appearance of the end-organ in the hearing adult (Fig. 15 Isolde) is in sharp contrast to that found in all the deaf ears This picture of cochlear duct degeneration is already well advanced by day twenty (Fig 15 Polyxena) and is thereafter progressive with age. The spiral ganglion in the ten month deaf ear (Fig. 15 Ulysses) is very similar to that of the hearing adult (Fig. 15 Isolde) and it is first at the nineteen month stage (Fig. 15 Helena) that a reduction in number of neurons becomes readily apparent The density of the spiral ganglion cell population in Rosenthal's canal decreases progressively with age (Fig 15 Circe & Romeo) In Fig 16 are shown higher power views of the spiral ganglions already presented in the previous illustration The progressive ganglion cell loss and degeneration of the afferent nerve fibres with age are immediately apparent.

In Fig 17 are shown high power views of the areas marked by arrows in the previous figure The spiral ganglion cells of the hearing adult (Fig 17 Isolde) have a characteristic appearance with well differentiated Nissl substance. In the twenty day (Fig 17 Polyxena) and the ten month (Fig 17 Ulysses) deaf animals some of the

Fig. 17. Higher power views of ganglion cells marked by arrows in Fig. 16. Normal appearance of spiral ganglion cells in the hearing adult cat (Isolde). Chromatolysis is evident in some of the ganglion cells in the 20 day (Polyxena) and 10 month (Ulysses) deaf ears, but others contain Nissl granules and have normal appearing nuclei. In the 19 month (Helena), 28 month (Circe) and 8 year (Romeo) deaf ears are found scattered ganglion cells which are larger with homogeneous, occasionally vacuolar cytoplasm and densely staining nuclei.

subsequent compression of the ganglion cells. All three ears at the ten month stage have total neuron counts at the lower limit of the range of normal. In all deaf ears from cats over the age of ten months there is a significant reduction in total neuron count, and this correlates approximately with the age of the animal. The total neuron count of the functional and pathological ears are presented graphically in Fig. 18.

Table 15 also demonstrates that ganglion cell loss occurs first in the central portion of the spiral ganglion segments BC, CD and DE, and this area is consistently the most severely affected. The greatest absolute and relative degree of ganglion cell loss is found in segment CD, i.e. the upper half of the basal coil, in the two oldest animals in the series (Alpha & Romeo).

DISCUSSION

Estimations of the total number of neurons in the spiral ganglion of the cat have varied con-

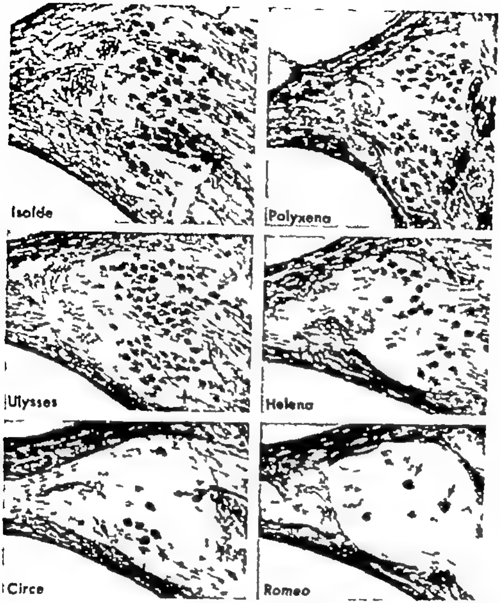

Fig 16 Higher power views of spiral ganglions from the preceding figure. Ganglion cell densities are approximately similar in the hearing adult (Isolde), the 20 day deaf (Polyxena) and the 10 month deaf (Ulysses) ears, whereas progressive ganglion cell loss with increasing connective tissue replacement are found in the 19 month (Helena), 28 month (Circe) and 8 year (Romeo) deaf animals. Arrows mark areas shown in succeeding figure.

similar in the central segments BC, CD and DE. At both extremities, segments AB and FG the mean densities are higher and there is a significantly greater range of variation

The total neuron counts and the neuron densities of forty-eight pathological ears are shown in Table 15 The data are presented in ascending age groups up to and including the ten month stage and are thereafter arranged in ascending order of ganglion cell loss. This is found to correspond closely with the age of the animal It should be noted that the exact ages of the adult (over two years) deaf animals were unfortunately not known but the oldest, Romeo was at least two years older than the rest of the series. Up to and including the six month deaf animal the total neuron counts are almost entirely within the range of normal presented in Table 14 In only one instance Ino ııı the total count of 44 355 slightly below the lower limit of 45 020 found in the series of normals Ganglion cell counts in young animals are difficult and more liable to inaccuracies due to the plentiful vascularisation in the modiolus at this stage with

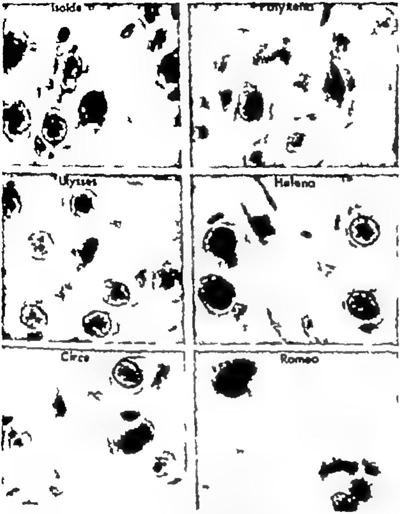

Fig 17 Higher power view of ganglion cells marked by arrow in Fig 16 Normal appearance of spiral ganglion cells in the hearing adult cat (Isolde) Chromatolysis is evident in some of the ganglion cells in the 20 day (Polyxena) and 10 month (Ulysses) deaf ears, whilst others contain Nissl granules and have normal appearing nuclei In the 19 month (Helena), 28 month (Circe) and 8 year (Romeo) deaf ears are found scattered ganglion cells which are larger with homogeneous, occasionally vacuolar cytoplasm and densely staining nuclei.

subsequent compression of the ganglion cells. All three ears at the ten month stage have total neuron counts at the lower limit of the range of normal In all deaf ears from cats over the age of ten months there is a significant reduction in total neuron count, and this correlates approximately with the age of the animal. The total neuron counts of the functional and pathological ears are presented graphically in Fig 18.

Table 15 also demonstrates that ganglion cell loss occurs first in the central portion of the spiral ganglion, segments BC, CD and DE, and this area is consistently the most severely affected The greatest absolute and relative degree of ganglion cell loss is found in segment CD i.e. the upper half of the basal coil, in the two oldest animals in the series (Alpha & Romeo)

DISCUSSION

[a] Contralateral ear normal
[b] Every fifth section counted

siderably. In studies based on ganglion cell counts, Howe (1935) found a range of normal of 44 798 to 57 494, with a mean value of 49 962 for a series of nine ears, whilst Schuknecht (1960) reported the much lower figure of 39 000. Analysis of the myelinated fibres in the cochlear nerves of six cats produced an average of 51 755 (Gacek & Rasmussen, 1961), which is remark

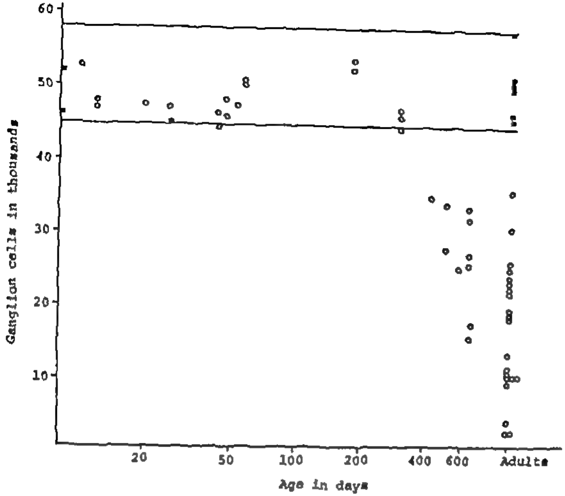

Fig. 18. Total ganglion cell counts of seventeen hearing and forty-eight deaf ears. Age is represented logarithmically along the abscissa and ganglion cell counts in thousands along the ordinate. The range of normal for this series is shown by the two horizontal lines. ● = ganglion cell count in hearing ear. O = ganglion cell count in deaf ear.

ably similar to the figure of 51 770 from the present series of seventeen ears. The slightly higher figure of 55 000 has been reported by Spoendlin (1972) on the basis of fibre counts in the osseous spiral lamina.

The mean length of the spiral ganglion in this material, 10.67 mm, is close to the figure of 11.2 mm reported by Schuknecht (1960). A higher neuron density in the central portion of the human spiral ganglion was found by Guild (1932) and in the cat by Spoendlin (1972) whereas Schuknecht (1960) reported that the neuron population densities in the latter species were uniform throughout the length of the spiral ganglion. The present material supports the latter finding, but demonstrates a slightly greater density at both extremities of Rosenthal's canal. This may represent compensation for the greater length of the cochlear duct and the unequal representation of the latter along the shorter spiral ganglion (Sando 1965). The greater variability in neuron densities found in the hook region and at the apex are probably a result of the investigational technique and counting based on studies of consecutive sections instead of every tenth or fifth would almost certainly reveal a greater uniformity.

The degeneration pattern of the structures in the cochlear duct of the deaf white cat has been previously shown to be closely related to the age of the animal (Mair III). Degeneration commences at the end of the first postnatal week, progresses rapidly in the subsequent two to three weeks, and thereafter more slowly through

out the animal's life span. In the six month deaf cat the organ of Corti shows an advanced degree of degeneration of all cell types, but the nerve fibres in the osseous spiral lamina reveal no abnormalities on light microscopy and the ganglion cell count is within the range of normal. By ten months, the neuron counts of the three ears in this series are at, or slightly below the lower limit of the range of normal, but in the next age group represented, fourteen months, the ganglion cell count is already reduced by approximately 30%. Increasingly older animals show a successively greater reduction in total ganglion cell numbers, and by eight years (Romeo) only 6% of the neurons remain. The two ears of bilaterally deaf animals show an approximately symmetrical degeneration pattern, the differences in ganglion cell counts which occur being well within the range of variability found in the hearing animals. This bilateral symmetry is not surprising in view of the symmetrical end-organ degeneration found in the cochlea (Mair III).

A similar pattern of a primary end-organ degeneration and a delayed degeneration of the afferent cochlear neurons has been reported in several mouse mutants (Grüneberg, 1955; Deol, 1970) and in the waltzing guinea pig (Ernstson, 1971). Statistical evidence in the form of ganglion cell counts correlated with age is, however, lacking in the literature. Only in three mouse mutants have quantitative studies in the form of ganglion cell densities per unit area of the spiral ganglion been made (Deol, 1954). The latter author demonstrated a progressive ganglion cell loss, which continued throughout life although the rate of degeneration was less in the older animals. In one species of mouse, varitint-waddler, the spiral ganglion degeneration was found to occur prior to changes in Corti's organ, but it is possible that electron microscopy would clarify this apparent exception.

Normal cochlear neurons have been reported in the deaf dalmatian dog (Bredberg, 1968), and in only one of the animals studied by Anderson et al. (1968) was a reduction of spiral ganglion cells found. Schuknecht et al. (1965) also found a normal neuron density in the deaf dalmatian dog and considered that the degenerative changes in the cochlear duct must have occurred during embryological development, adducing as evidence the rapid secondary neuronal degeneration which occurs subsequent to acquired, postnatal lesions of the end-organ (Schuknecht, 1953). By implication, the cochleo-saccular degeneration in the deaf dalmatian dog would therefore be classified in Grüneberg's (1955) morphogenetic group. Comparison with the morphologically similar cochleo-saccular degeneration in the white cat would tend to refute this suggestion, as it is clearly demonstrated in the present material that neuronal and end-organ degeneration are separated by a considerable interval of time. That such a comparison is valid is shown by the earlier report of spiral ganglion cell degeneration in all deaf dalmatian dogs studied by Lurie (1948). There is probably considerable inter-species variation in the time-course of hereditary cochleo-saccular degeneration, normality of the spiral ganglion having been reported until late in adult life in human material (Gacek, 1971).

Both the postnatal maturation of the normal cat cochlea and the process of cochlear end-organ degeneration in the deaf white cat commence in the upper half of the basal coil and extend longitudinally along the cochlear duct (Mair III). Degeneration of the spiral ganglion cells also shows a similar spatial distribution. Table 15 demonstrates that ganglion cell loss is first evident in the upper basal coil around the age of ten months, and this site of predilection remains the most severely affected, both extremities of the ganglion being relatively better preserved in the deaf adult. In the eight year deaf adult (Romeo), the neuron densities expressed as a percentage of the mean density per mm of the normal hearing cochlea are 1.6% in the upper basal coil, and respectively 15.3% and 19.2% in the hook region and at the apex. In the mouse mutants mentioned above, the spiral ganglion degeneration was found to commence in the "basal half-turn" and to spread along the duct towards the apex (Deol, 1954). Spiral ganglion cell loss restricted to the middle coil has been

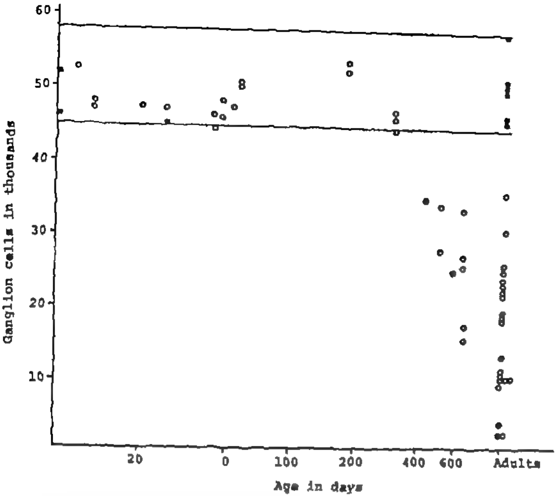

Fig 18 Total ganglion cell counts of seventeen hearing and forty-eight deaf ears. Age is represented logarithmically along the abscissa and ganglion cell counts in thousands along the ordinate. cells remain, and this figure is similar to the number of type II neurons. However the majority of the surviving neurons appear unhealthy and it seems not improbable that longer survival periods would reveal even lower ganglion cell counts. If this supposition is correct, then both type I and type II ganglion cells undergo degeneration following hereditary end-organ degeneration, although differing time patterns is a possibility. The distribution of the surviving ganglion cells, with considerably greater preservation at the apex and the hook region, would also appear to support this theory since the type II ganglion cells, which give rise to the basilar tunnel fibres (Spoendlin, 1972), have presumably a more or less constant density throughout the cochlea.

The presence of a slight degree of chromatolysis in some ganglion cells at the twenty day stage demonstrates that neuronal degeneration commences prior to hair cell loss. However significant loss of ganglion cells does not occur until one year later. Approximately 50% of the neurons survive at the end of the second year and thereafter the rate of ganglion cell loss slows down appreciably. The time pattern of cochlear degeneration in hereditary deafness is of prime importance in deciding the success or failure of electrode implantation in the treatment of human sensorineural hearing loss. Electrical stimulation by either perilymphatic or modiolar electrodes (Simmons & Glattke, 1972) is doomed to failure if the afferent neurons have already degenerated. Further study of cochlear end-organ and neuronal degeneration patterns in animals and man is therefore urgently required.

ZUSAMMENFASSUNG

Der Degenerationsprozess im Spiralganglion der erblich tauben weissen Katze wurde in verschiedenen Altersklassen quantitativ untersucht. Es wurden Cochleagang und Spiralganglion beim erblich tauben und pathologisch veränderten Ohr zeichnerisch rekonstruiert; die durchschnittliche Länge des Spiralganglions betrug 10.67 mm und die durchschnittliche Gesamtzahl Neuronen betrug 31 770 beim funktionstüchtigen und histologisch normalen Ohr.

Ein Verlust an Spiralganglionzellen bei tauben Tieren trat statistisch signifikant erstmals nach 10 Monaten ein und nahm danach laufend weiter mit zunehmendem Alter ab. Der zentrale Ganglionabschnitt zeigte den grössten Verlust an Neuronen, während an beiden Enden des Rosenthalschen Kanals der Neuronenbestand rel. länger erhalten blieb.

Kimura, R. S. 1967. Experimental blockage of the endo-

reported in the deaf dalmatian dog (Anderson et al 1968) and in the upper basal coil of the deaf Border collie (Igarashi et al 1972) The latter authors considered this region to be the most fragile part of the end-organ whilst Anderson et al. (1968) proposed that embryological factors might account for the preferential locali sation of the degenerative process

Ruben (1967) has demonstrated by a radio-autographic study that the youngest cells of the organ of Corti are found in the basal coil and the oldest at the apex In the previously reported study of the cochlear histopathology in the white cat (Mair III) it was postulated that this aspect of the embryological development of the cochlea might help to explain the earlier occurrence of the degenerative process in the upper basal coil If this hypothesis is correct then neuronal degeneration is clearly secondary to hair cell degeneration since the oldest spiral ganglion cells are found in the basal and the youngest in the apical portions of the cochlea i.e the reverse of the arrangement in Corti s organ (Ruben 1967)

Degeneration of the more basal end of the spiral ganglion has been described in presbycusis (Schuknecht, 1955 Bredberg 1968), in hereditary human deafness (Beal et al 1967) and in presumed viral labyrinthitis (Lindsay Davey & Ward 1960) Apical coil degeneration occurs less frequently but has been reported in labyrinthine hydrops, both in the human (Kohut & Lindsay 1972) and in experimental material (Kimura, 1967) A similar apical spiral ganglion degeneration has been described in experimental obstruction of the labyrinthine vascular supply (Bernstein & Schuknecht, 1967) No abnormalities were found in the cochlear vascular system in the present series, and neither cochlear nor saccular hydrops was found to be a feature of the degenerative process. The markedly differing spiral ganglion degeneration patterns found in hydrops and in the hereditary deafness of the white cat may be additional evidence that volume oscillations of the endolymphatic duct due to hydrops are not typical of this degeneration process.

On the basis of experimental results from acute lesions to the organ of Corti it has for many years been maintained that spiral ganglion cell degeneration was secondary to loss of or damage to the supporting elements of Corti's organ primarily the pillar cells (Schuknecht, 1953 Spoendlin & Gacek, 1963) More recently a closer inter relationship has been demonstrated between inner hair cell loss and degeneration of the afferent neurons (Bredberg, 1968) A probable explanation for this latter theory is provided by the demonstration of two different cell populations in the spiral ganglion

Two types of ganglion cells have been previously reported in the spiral ganglion of the rat (Rosenbluth 1962) and the guinea pig (Kellerhals, Engstrom & Ades, 1967) but it was not until 1971 that a similar situation was demonstrated in the cat Spoendlin & Gacek (1963) had earlier transected the cochlear nerve in the internal auditory meatus and reported that the outer spiral fibres and terminals to the outer hair cells persisted despite degeneration of almost all the ganglion cells in Rosenthal s canal. Spoendlin (1971) re-examined the temporal bones from these transection experiments and found some neurons which had the morphological characteristics of type II ganglion cells This finding was then corroborated in an electron microscopy study of the ganglion in hearing animals

In the guinea pig no special relationship was found between the two types of ganglion cells and the inner and outer hair cells (Kellerhals et al 1967) whereas in the cat a specific innervation pattern was found (Spoendlin 1971) In the latter species, the type I cells, constituting 95 % of the total ganglion cell population innervate exclusively the inner hair cells and undergo retrograde degeneration following nerve section in the internal meatus On the other hand the type II cells are smaller considerably fewer in number only 5 % of the total, innervate mostly the outer hair cells, and apparently resist retrograde degeneration (Spoendlin 1971 1972)

In the oldest animal in the present series, Romeo eight years, only 6 of the ganglion

1 Introduction

Although the vestibular system has been ex tensively studied the function of the individual vestibular nuclei is still not clear (For reviews of recent and older studies see Camis & Creed 1930 Brodal et al 1962 Kornhuber 1966 Cohen 1971 Brodal & Pompeiano 1972) Moreover signs of lesions of individual vestibular nuclei or of parts of the vestibular nuclear complex are not well understood (Buchanan, 1940 Ferraro et al 1940 Scala & Spiegel 1941 Crammer 1951 Shanzer & Bender 1959 Abe 1960 Carpenter et al 1960) Four aspects of structural and functional organization have been demonstrated in recent studies

(1) Primary afferents from the semicircular canals and the otolith organs have a partially common and partially separate distribution in the vestibular nuclei (Lorente de Nó 1933 Stein & Carpenter 1967 Gacek 1969) The semicircular canals send axons mainly to the superior vestibular nucleus (SVN) the rostral medial vestibular nucleus (MVN) and the lateral vestibular nucleus (LVN) while the otolith organs project axons primarily to LVN caudal MVN and the descending vestibular nucleus (DVN) This implies that activity arising in the semicircular canals and otolith organs carrying information about angular head movements or about static head position and linear head movement is processed in different parts of the vestibular nuclei In apparent agreement with this neurons which respond to angular acceleration are mainly found in rostral portions of the vestibular nuclei while units which respond to head tilt occur more frequently in central and caudal portions of the vestibular nuclei (Adrian 1943 Duensing & Schaefer 1958 Shimazu & Precht 1965 Fujita et al 1968 Peterson 1970) Whether lesions in these regions would disturb semicircular canal or otolith organ function is not known

(2) Efferent vestibular pathways have been studied by a number of workers (Szentágothai 1950 1964 Brodal & Pompeiano 1957 a 1957 Brodal & Torvik, 1957 Carpenter et al 1959 Carpenter 1960 Brodal et al 1962 McMasters et al 1966 Tarlov 1969 1970 Gacek, 1971) SVN rostral MVN and ventral LVN receive primary afferent fibers from the semicircular canals and have direct connections to the eye muscle motor nuclei From this it has been inferred that these regions play an important role in mediating vestibulo-ocular reflexes from the semicircular canals An otolith organ projection has also been found in rostral MVN which in turn has connections to the oculomotor nucleus (Gacek, 1969 1971) Recently Highstein (1971 1973 a) Highstein and Ito (1971) and Highstein et al (1971) have shown that SVN mediates only inhibition in all of its known connections while rostral MVN mediates both excitation and inhibition (Baker et al. 1969 Highstein, 1973 a b). The effects of SVN rostral MVN and ventral LVN lesions on vestibulo-ocular reflexes are not known

(3) There are abundant connections between the vestibular nuclei on both sides of the brainstem According to Ladpli & Brodal (1968) these are separated into two groups One originates in the superior nucleus and the *ventral* parts of the other three main nuclei The other projection comes from the *descending* nucleus and ends chiefly in the ventral parts of the contralateral vestibular nuclei. Shimazu & Precht (1966) have shown the importance of commissural fibers in mediating crossed inhibition onto cells in the vestibular nuclei on the contralateral side.

CONTENTS

1 Introduction

Although the vestibular system has been extensively studied the function of the individual vestibular nuclei is still not clear (For reviews of recent and older studies see Camis & Creed 1930 Brodal et al 1962 Kornhuber 1966 Cohen 1971 Brodal & Pompeiano 1972) Moreover signs of lesions of individual vestibular nuclei or of parts of the vestibular nuclear complex are not well understood (Buchanan 1940 Ferraro et al 1940 Scala & Spiegel 1941 Cranmer 1951 Stanzer & Bender 1959 Abe 1960 Carpenter et al 1960) Four aspects of structural and functional organization have been demonstrated in recent studies.

(1) Primary afferents from the semicircular canals and the otolith organs have a partially common and partially separate distribution in the vestibular nuclei (Lorente de Nó 1933 Stein & Carpenter 1967 Gacek 1969) The semicircular canals send axons mainly to the superior vestibular nucleus (SVN) the rostral medial vestibular nucleus (MVN) and the lateral vestibular nucleus (LVN) while the otolith organs project axons primarily to LVN caudal MVN and the descending vestibular nucleus (DVN) This implies that activity arising in the semicircular canals and otolith organs carrying information about angular head movements or about static head position and linear head movement is processed in different parts of the vestibular nuclei. In apparent agreement with this neurons which respond to angular acceleration are mainly found in rostral portions of the vestibular nuclei while units which respond to head tilt occur more frequently in central and caudal portions of the vestibular nuclei (Adrian 1943 Duensing & Schaefer 1958 Shimazu & Precht 1965 Fujita et al. 1968 Peterson 1970) Whether lesions in these regions would disturb semicircular canal or otolith organ function is not known

(2) Efferent vestibular pathways have been studied by a number of workers (Szentágothai 1950 1964 Brodal & Pompeiano 1957 *a* 1972 Brodal & Torvik, 1957 Carpenter et al 1959 Carpenter 1960 Brodal et al 1962 McMasters et al 1966 Tarlov 1969 1970 Gacek 1971) SVN rostral MVN and ventral LVN receive primary afferent fibers from the semicircular canals and have direct connections to the eye muscle motor nuclei From this it has been inferred that these regions play an important role in mediating vestibulo-ocular reflexes from the semicircular canals An otolith organ projection has also been found in rostral MVN which in turn has connections to the oculomotor nucleus (Gacek, 1969 1971) Recently Highstein (1971 1973 *a*) Highstein and Ito (1971) and Highstein et al (1971) have shown that SVN mediates only inhibition in all of its known connections while rostral MVN mediates both excitation and inhibition (Baker et al 1969 Highstein, 1973 *a b*) The effects of SVN rostral MVN and ventral LVN lesions on vestibulo-ocular reflexes are not known.

(3) There are abundant connections between the vestibular nuclei on both sides of the brainstem. According to Ladpli & Brodal (1968) these are separated into two groups 'One originates in the superior nucleus and the ventral parts of the other three main nuclei. The other projection comes from the descending nucleus and ends chiefly in the ventral parts of the contralateral vestibular nuclei" Shimazu & Precht (1966) have shown the importance of commissural fibers in mediating crossed inhibition onto cells in the vestibular nuclei on the contralateral side

However there is little information about how eye movements would change if these fibers were interrupted

(4) Beyond the vestibular nuclei the separation of activity which arises in otolith organs and semicircular canals is maintained in many of the pathways through the pons and cerebellum to the oculomotor nuclei (see Carpenter 1971 Cohen 1971) How signs of lesions in the vestibular nuclei might differ from those of lesions in extra nuclear pathways is not known in many instances

The purpose of this research is to describe oculomotor changes produced by discrete lesions of the vestibular nuclei with the use of electro-oculography (EOG) By integrating these data with those from recent anatomic and physiologic studies it is hoped that a clearer idea of the function of the vestibular nuclei will emerge

2 Material and Methods

Thirty juvenile rhesus monkeys of 2 to 4 kg were used in these experiments. Animals were tested by using electro-oculography (EOG) to establish whether their spontaneous eye movements and induced nystagmus were normal (Komatsuzaki et al., 1969). Bipolar electrodes made of 0.25 mm insulated stainless steel wire with a 1 or 2 mm tip separation were introduced in horizontal stereotaxic planes into the region of the vestibular nuclei under anesthesia. Ocular responses to vestibular nuclei stimulation were used to aid in final placement of electrodes (Cohen et al., 1965 *a*; Tokumasu et al., 1969). Electrodes were cemented to the skull. Eye movements induced by electrical stimulation were observed after operation. The animals were also retested to determine effects of implantation on vestibulo-ocular reflexes.

Lesions were made by passing 5–10 mA of current through one or both of the electrodes for 15–60 seconds. Except where specified lesions were all on the left. Eye movements were observed and recorded by using EOG and cinematography. Animals were also photographed while sitting or climbing. They were tested until recovery or until there was no further change in vestibulo-ocular reflexes on several test occasions. The labyrinth on the side contralateral to the lesion was usually destroyed. This was done in order to selectively stimulate the labyrinth on the lesion side with positional tests. The cristae and nerves of the anterior, lateral and posterior semicircular canals, and the maculae and nerves of the utricle and saccule were identified and removed using an operating microscope. Animals were retested for another month.

Monkeys were killed with an overdose of barbiturates, and were perfused through the heart with saline and 10% formalin. After fixation in formalin, the brainstem and cerebellum were removed from the skull, embedded in celloidin, and sectioned in vertical stereotaxic planes. Alternate 40 µm sections were stained with cresyl violet and Weil stains. The lesions were drawn and photographed. Diagrams of representative sections through the vestibular nuclei in vertical stereotaxic planes separated by 0.5 mm are shown in Fig. 1. Microphotographs of representative sections through the vestibular nuclei 1.5 mm apart are shown in Fig. 2. The four main vestibular nuclei (Brodal & Pompeiano, 1957 *b*) and surrounding structures are labelled in these sections.

Techniques of electro-oculography (EOG)

Monkeys were tested while restrained in a primate chair. Animals received amphetamine sulfate (0.5 mg/kg) 30 min before testing to maintain a constant level of alertness. Horizontal and vertical eye movements were recorded using platinum needle electrodes inserted in the skin around the eyes. The horizontal EOG was registered binocularly from electrodes at the outer canthus of each eye using d.c.-coupling. The vertical EOG was a monocular recording from electrodes above and below each eye. It was taken using r.c. coupling with a 5 sec time constant. The EOGs were registered on an oscillograph and recorded on FM magnetic tape. The EOG was differentiated by amplifiers with a 3 msec time constant to obtain the velocity of eye movements. The differentiated EOG was rectified and amplified to measure the velocity of slow phases of nystagmus. Slow phase velocity was integrated to determine total

However there is little information about how eye movements would change if these fibers were interrupted

(4) Beyond the vestibular nuclei the separation of activity which arises in otolith organs and semicircular canals is maintained in many of the pathways through the pons and cerebellum to the oculomotor nuclei (see Carpenter 1971 Cohen 1971) How signs of lesions in the vestibular nuclei might differ from those of lesions in extra nuclear pathways is not known in many instances

The purpose of this research is to describe oculomotor changes produced by discrete lesions of the vestibular nuclei with the use of electro-oculography (EOG) By integrating these data with those from recent anatomic and physiologic studies it is hoped that a clearer idea of the function of the vestibular nuclei will emerge

Fig. 2. Representative sections through the rostral (*top*), central (*middle*), and caudal (*bottom*) portions of the left vestibular nucleus of a normal monkey. The major subdivisions and adjacent structures are shown in the diagrams on the right. They correspond to sections C, F and I of Fig. 1 and are separated by 1.5 mm. Cresyl violet (1st column) and Weil (2nd column) stains.

deviation of the eyes. In all figures eye movements to the right or upward cause upward pen movements.

The EOG was calibrated by having the animal look between lights 15° and 30° apart alternately turned on and off or from slow phase velocity during OKN (Aschoff & Cohen, 1971). It was assumed that normal animals followed the OKN drum accurately at velocities up to 60°/sec. The calibration of the EOG was done in the normal animal and was assumed not to change during the period of observation. The calibration of the EOG varies in light and darkness. However each animal was tested under similar conditions before and after operation so that the results were comparable even if the EOG calibrations in darkness were approximate. Generally 22° of deviation caused about 1 mV of pen deflection in the EOG.

Examinations which were performed included tests for·

1 *Spontaneous nystagmus and positional nystagmus* Animals were tested for spontaneous nystagmus seated upright in light and in darkness The direction of nystagmus was designated by the direction of the quick phases Left and right refer to the animal s left or right Clockwise or counterclockwise rotation is designated from the point of view of the observer

To elicit positional nystagmus animals were placed on their right and left sides and upside down in light and in darkness Nystagmus was recorded by EOG and was observed with the monkey behind Frenzel glasses Animals were moved to the upright position after each test in lateral or upside-down positions

Interpretation of positional nystagmus

Not all nystagmus recorded in the various head positions was considered to be of equal significance as an index of abnormality in utriculo-ocular or sacculo-ocular reflex arcs. If positional nystagmus was elicited *de novo* or if it differed from the spontaneous nystagmus the lesion was considered to have had an important effect on otolith-ocular reflexes. An example of this would be apogeotropic or geotropic direction-changing positional nystagmus In apogeotropic nystagmus the quick phases are in the opposite direction to gravity (i e. to the right with the left side down and vice versa) During geotropic nystagmus the quick phases are directed toward the ground (i e. to the left with the left side down and vice versa) On the other hand, if the provoked nystagmus was similar to the spontaneous nystagmus but was only of different intensity the lesion was considered to have had a less significant effect on otolith-ocular reflexes An example would be direction-fixed positional nystagmus associated with spontaneous nystagmus in the same direction The persistence or fatigability of positional nystagmus was also noted.

2 *Caloric nystagmus* Caloric nystagmus was induced by injecting 15 ml of water into the external auditory canals over a 15 sec period The induced nystagmus was recorded in darkness In some instances it was observed in light and photographed Water temperatures of 27°C and 47°C were used most often for caloric stimulation These are 10°C below and above the monkey s body temperature

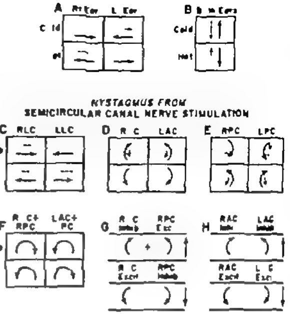

Fig 3 Directions of nystagmus which would be expected during unilateral (A) or bilateral (B) caloric stimulation or during excitation and inhibition of activity in semicircular canal nerves (C H). C–E show nystagmus from single semicircular canal stimulation and F G from simultaneous stimulation of both anterior and posterior canal nerves on one side. H is the nystagmus induced by bilateral anterior canal nerve excitation or inhibition and corresponds to the nystagmus shown in B The thin dotted arrows show the direction of eye movement during slow phases of nystagmus. The heavy solid arrows show the direction of the quick phases. The arrows representing the slow phases have been omitted from F–H The nystagmus is represented as seen by the observer i.e ⟶ is nystagmus with slow phases to the animal s right and quick phases to the animal's left *RAC* right anterior canal *LAC* left anterior canal *RLC* right lateral canal *LLC* left lateral canal *RPC* right posterior canal *LPC* left posterior canal

During caloric irrigation the head was extended so that the horizontal canals were approximately in the vertical plane The animals were also stimulated when upside down with the horizontal canals vertical To induce vertical nystagmus both ears were stimulated simultaneously with hot or with cold water with the animals upright. To evaluate caloric nystagmus the direction was noted and the duration maximum slow phase velocity and total deviation were measured Maximum slow phase velocity was defined as the mean of 10 beats with the highest velocity

Interpretation of horizontal caloric nystagmus

With animals upright, stimulation of one ear with cold water induces nystagmus to the contralateral side which is mainly horizontal, and stimulation with hot water causes the opposite reaction. With animals upside down the horizontal component induced by stimulation with cold water is the reverse of that in the upright position due to reversal of convection currents in the endolymph. However vertical and rotatory components are enhanced when the animal is upside down.

By comparing nystagmus induced by caloric stimulation to nystagmus induced by electrical stimulation of individual semicircular canal nerves (Fig. 3 Suzuki et al., 1964, Suzuki & Cohen, 1964 Cohen et al., 1965 *b*), it is possible to infer whether there had been an increase or decrease in neural activity in the ampullary nerves during caloric stimulation. The caloric responses from stimulation of either ear with hot or cold water are shown in Fig. 3A. Nystagmus induced by increasing activity in the individual semicircular canal nerves (excitation) is shown in Fig. 3C–E, Excit. The dotted arrows show the direction of the tonic deviations or slow phases of nystagmus and the solid arrows the direction of the quick phases of nystagmus. The reverse nystagmus would be expected from reduction of activity in these nerves (inhibition) (Fig. 3C–E, Inhib.).

From comparison of Fig. 3A and 3C it can be inferred that ipsilateral nystagmus induced by hot stimulation is due to an increase in activity in the ampullary nerves and contralateral nystagmus induced by cold caloric stimulation is due to decrease in activity. This is true with the animal in the upright position. The reverse would hold during caloric stimulation with the animal upside down.

Interpretation of vertical caloric nystagmus

Bilateral simultaneous cold caloric stimulation causes upward nystagmus in the mid-sagittal plane and bilateral hot stimulation, downward nystagmus (Fig. 3B). This nystagmus is normally very intense in the monkey. There is no rotatory component to the vertical nystagmus when the eyes are in the mid-position. It is possible to infer which canals produce the vertical response by comparison with the results of electrical stimulation.

(1) When the anterior and posterior semicircular canal nerves on one side are electrically excited, the eyes tort or roll without much upward or downward component (Fig. 3F). If all four vertical canals are electrically excited, there is no eye movement (Cohen et al., 1964). Thus the vertical nystagmus induced by bilateral hot or bilateral cold stimulation could not have been induced by simultaneous excitation nor simultaneous inhibition of all four vertical canals. Therefore the anterior and posterior canal nerves on one side could not have been simultaneously excited or inhibited during unilateral caloric stimulation. Either activity was increased in one canal nerve (excitation) and decreased in the other (inhibition), or only one vertical canal was affected.

(2) If unilateral caloric stimulus had caused a simultaneous decrease of activity in one anterior canal nerve and an increase in the posterior canal nerve or vice versa, the expected nystagmus would be straight up or down without rotatory components (Fig. 3G). However if unilateral caloric stimulation induces any response other than horizontal it is usually primarily rotatory and vertical components are much less prominent. Moreover pure vertical nystagmus is never produced by unilateral stimulation. Thus it seems unlikely that a unilateral caloric stimulus simultaneously affects two vertical canals on the stimulated side in any combination.

(3) The single vertical canal most likely to be affected by caloric stimulation is the anterior canal. It lies close to the ear drum, and would be stimulated concurrently with the lateral canal. The posterior canals lie deeper in the middle ear further from the drum. From the preceding argument, we would postulate that upward nystagmus caused by bilateral cold irrigation (Fig. 3B, Cold) is due to inhibition of activity in the nerves of both anterior canals (Fig. 3H Inhib) and downward nystagmus induced by bilateral hot irrigation (Fig. 3B Hot) is due to excitation in these same nerves (Fig. 3H Excit). If the preceding arguments are correct, there is little effect of the caloric stimulus on the posterior canals.

Although both anterior and lateral canals must be simultaneously activated by single caloric stimulus, the horizontal response predominates. Only when the horizontal canal responses are mutually inhibited as during bilateral stimulation do the anterior canal responses become manifest. Other evidence that the horizontal and anterior canals are mainly responsible for caloric nystagmus will be considered subsequently in the General Discussion (Chapter 10).

3 *Optokinetic nystagmus (OKN)* Optokinetic nystagmus (OKN) was induced by a servo-controlled optokinetic drum which surrounded the animal, and filled its field of vision. Four speeds of drum rotation were commonly used for testing: 45°/sec, 63°/sec, 90°/sec and 135°/sec. Monkeys were stimulated for 60 sec at each velocity. Mean maximum slow phase velocity was used to determine the intensity of OKN in a particular direction. To test for optokinetic after-nystagmus (OKAN), OKN was induced by drum rotation at 60°/sec or 90°/sec for 30 sec. The the lights were extinguished and OKAN was recorded in darkness.

4 *Positional alcohol nystagmus (PAN)* After alcohol ingestion animals were tested

Examinations which were performed included tests for

1 *Spontaneous nystagmus and positional nystagmus* Animals were tested for spontaneous nystagmus seated upright in light and in darkness The direction of nystagmus was designated by the direction of the quick phases Left and right refer to the animal s left or right Clockwise or counterclockwise rotation is designated from the point of view of the observer

To elicit positional nystagmus animals were placed on their right and left sides and upside down in light and in darkness Nystagmus was recorded by EOG and was observed with the monkey behind Frenzel glasses Animals were moved to the upright position after each test in lateral or upside-down positions

Interpretation of positional nystagmus

Not all nystagmus recorded in the various head positions was considered to be of equal significance as an index of abnormality in utriculo-ocular or sacculo-ocular reflex arcs. If positional nystagmus was elicited *de novo* or if it differed from the spontaneous nystagmus, the lesion was considered to have had an important effect on otolith-ocular reflexes. An example of this would be apogeotropic or geotropic direction-changing positional nystagmus In apogeotropic nystagmus the quick phases are in the opposite direction to gravity (i e to the right with the left side down and vice versa) During geotropic nystagmus the quick phases are directed toward the ground (i e. to the left with the left side down and vice versa).On the other hand if the provoked nystagmus was similar to the spontaneous nystagmus but was only of different intensity the lesion was considered to have had a less significant effect on otolith-ocular reflexes. An example would be direction-fixed positional nystagmus associated with spontaneous nystagmus in the same direction The persistence or fatigability of positional nystagmus was also noted.

2 *Caloric nystagmus* Caloric nystagmus was induced by injecting 15 ml of water into the external auditory canals over a 15 sec period The induced nystagmus was recorded in darkness In some instances it was observed in light and photographed Water temperatures of 27°C and 47°C were used most often for caloric stimulation These are 10°C below and above the monkey s body temperature

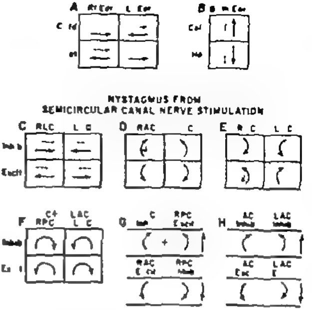

Fig 3 Directions of nystagmus which would be expected during unilateral (A) or bilateral (B) caloric stimulation or during excitation and inhibition of activity in semicircular canal nerves (C–H). C–E show nystagmus from single semicircular canal stimulation and F G from simultaneous stimulation of both anterior and posterior canal nerves on one side H is the nystagmus induced by bilateral anterior canal nerve excitation or inhibition and corresponds to the nystagmus shown in B The thin dotted arrows show the direction of eye movement during slow phases of nystagmus The heavy solid arrows show the direction of the quick phases. The arrows representing the slow phases have been omitted from F–H The nystagmus is represented as seen by the observer I.e ⟵ is nystagmus with slow phases to the animal s right and quick phases to the animal s left. *RAC* right anterior canal *LAC* left anterior canal *RLC* right lateral canal *LLC* left lateral canal *RPC* right posterior canal *LPC* left posterior canal

During caloric irrigation the head was extended so that the horizontal canals were approximately in the vertical plane The animals were also stimulated when upside down with the horizontal canals vertical To induce vertical nystagmus both ears were stimulated simultaneously with hot or with cold water with the animals upright To evaluate caloric nystagmus the direction was noted and the duration maximum slow phase velocity and total deviation were measured Maximum slow phase velocity was defined as the mean of 10 beats with the highest velocity

down. About 5 hours later the nystagmus reverses in most monkeys becoming apogeotropic direction-changing positional nystagmus (PAN II) In apogeotropic or antigravity nystagmus the quick phases are away from ground, being to the right with the left side down and vice versa. PAN II was not studied in these experiments

PAN was recorded in darkness. The slow phases of the nystagmus were integrated to determine the total deviation of the eyes over 20 sec periods If monkeys had spontaneous or positional nystagmus the intensity of PAN was estimated by adding or subtracting the intensity of this nystagmus to the PAN Fig. 5 shows the reproducibility of intensity of PAN on two occasions

Changes in posture Oculomotor changes were of primary interest in this study but postural effects were also noted. Animals were photographed one or several days after lesions when sitting upright or attempting to sit upright, and when climbing on a bar These postures are shown in appropriate places in the text and are summarized in Fig. 58 in the General Discussion

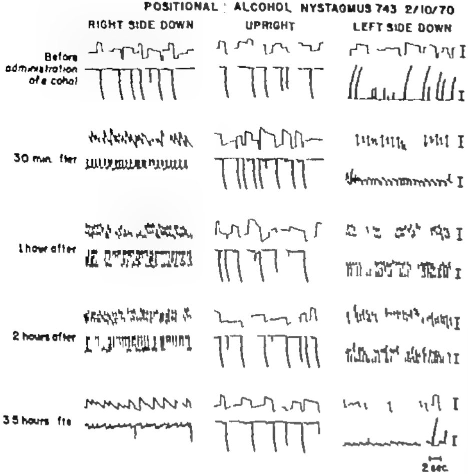

Fig 4 Positional alcohol nystagmus of a normal monkey during the first phase (PAN I) The top trace in each pair is the horizontal EOG and the bottom trace the differentiated rectified EOG showing slow phase velocity The calibrations are the vertical bars which are 20° for the EOG and 45°/sec for the differentiated EOG

for spontaneous nystagmus gaze nystagmus and positional nystagmus in lateral and upside down positions (PAN) PAN was used as a measure of the integrity of utriculo-ocular and sacculo-ocular pathways Monkeys were not fed before receiving alcohol and received the usual alerting dose of amphetamine (0 5 mg/kg) Pure ethanol (1 5 gm/kg) diluted 1 2 in water was introduced through a oro gastric tube PAN was tested 0 5 1 and 3 hours after ingestion of alcohol In the first phase (PAN I) the nystagmus is geotropic direction-changing positional nystagmus which reaches maximum intensity in about 1–1 5 hours (Figs 4 5) In geotropic positional nystagmus the quick phases are toward the ground being to the right with the right side down and to the left with the left side

Fig 5 Graph showing total deviation of eyes (ordinate) at various times during PAN of Monkey 743 on two separate test occasions The points were determined by measuring the total deviation of the eyes (integrated slow phase velocity) during 20 sec of the most active positional nystagmus Time after ingestion of alcohol is shown on the abscissa

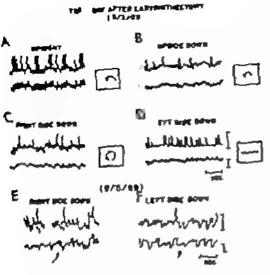

Fig 7 A–D, Spontaneous and positional nystagmus one day after left labyrinthectomy in 729 The upper trace in each pair is the vertical EOG and the lower trace the horizontal EOG The direction of the quick phases of nystagmus is shown in the diagram on the right. A, When the animal was upright, there was horizontal counter-clockwise rotatory spontaneous nystagmus to the contralateral side C, With the right side down the nystagmus was predominantly rotatory and D, with the left side down it was predominantly horizontal. B Counter-clockwise rotatory nystagmus was also found in the upside down position. E, F Positional nystagmus 3 days after left labyrinthectomy in 729 With the right side or left side down, there was horizontal component to the (left) ipsilateral side. This is indicated by the arrows below the bottom traces. The vertical bars show the calibration which is 15° for both the horizontal and vertical EOGs.

After labyrinthectomy ipsilateral OKAN initially disappeared and contralateral OKAN was decreased. For example the duration of OKAN was 44 sec to the right and left in 707 before right labyrinthectomy (Fig 8 A B) Four days after labyrinthectomy there was no OKAN to the ipsilateral side and only 13 sec of OKAN to the contralateral side Six days after operation the duration of OKAN was 3 sec to the ipsilateral (Fig 8 C) and 18 sec to the contralateral side (Fig 18 D). Findings were similar in 729

Alcohol (1.5 g/kg) induced positional alcohol nystagmus (PAN) to both sides after labyrinthectomy (Fig. 9 D F). The nystagmus was stronger to the contralateral side (Fig 9 F) However if the intensity of the spontaneous nystagmus (Fig. 9 E) was added to the PAN of Fig 9 D and subtracted from the PAN of Fig. 9 F then there was a relatively symmetrical effect of head position. This is shown by the graph of PAN after labyrinthectomy in Fig 10 (solid lines) In both monkeys the magnitude of changes in PAN was about half that of the original effect before labyrinthectomy

B *Bilateral labyrinthectomy* The second labyrinthectomy did not cause an ipsilateral head tilt in either monkey That is the head still remained slightly tilted to the side of the first labyrinthectomy (Fig. 8 B) There was some difficulty in holding the head upright, but no definite falling tendency to either side. Contralateral spontaneous nystagmus was present for 2 days in light and for about 1 week in darkness Spontaneous nystagmus was not affected by changes in head position before or after administration of alcohol (Fig. 9 G–I) but alcohol gaze nystagmus was still present.

OKN was initially somewhat asymmetrical after bilateral labyrinthectomy There was a decrease in the velocity of slow phases of ipsilateral OKN Moreover the animals could not follow well for OKN drum velocities above 60°/sec to either side for long periods of time (Cohen et al. 1973) OKAN could not be induced after bilateral labyrinthectomy in either animal although OKN was present (Fig. 8 E, F) The loss of OKAN after bilateral labyrinthectomy was permanent (Fig. 8 G H)

Comment

Signs after labyrinthectomy are similar to those reported previously (Magnus 1924 Northington & Barrera, 1934 Dow 1938) These included a head tilt and falling tendency toward the operated side a tendency to circle in that direction and spontaneous nystagmus toward the opposite side Recovery of postural asymmetry after unilateral labyrinthectomy

3 Labyrinthectomy

A *Unilateral labyrinthectomy* To provide a basis for comparing effects of central and peripheral vestibular lesions the labyrinths were destroyed in 2 animals (707 & 729) The results were similar in both monkeys After unilateral labyrinthectomy initially there was an ipsilateral head tilt (Fig 6 A) and the animals tended to fall toward the operated side The head tilt gradually recovered over about a month Dysequilibrium was not severe

There was horizontal rotatory nystagmus to the contralateral side in light for about 3 days in both animals After left labyrinthectomy the rotatory component of the spontaneous nystagmus was counterclockwise (Fig 7 A) Spontaneous nystagmus was present in darkness for 10 days in one animal and for more than 6 weeks in the other Although the predominant direction of the spontaneous nystagmus was contralateral (Fig 7 A–D) an ipsilateral horizontal component was present in the EOG 3–6 days after operation in both animals (Fig. 7 E F upward arrows) However ipsilateral horizontal nystagmus was not observed in light or behind Frenzel glasses

Changes in head position affected the spontaneous nystagmus after unilateral labyrinthectomy There was prominent contralateral horizontal nystagmus when the ipsilateral side was down (Fig 7 D) and rotatory nystagmus when the contralateral side was down (Fig 7 C) or when the animal was upside down (Fig 7 B)

OKN was induced in both directions after unilateral labyrinthectomy (Fig 8 C D) The velocity of the slow phases was initially less when the OKN was toward the ipsilateral side (Fig 8 C upward arrow) Directional preponderance persisted for about 2 weeks and was most prominent at higher drum velocities (≥90°/sec) After the directional preponderance disappeared the animal was unable to follow well at higher OKN drum velocities in either direction A more complete description of changes in OKN after labyrinthectomy is given elsewhere (Cohen et al 1973)

Optokinetic after-nystagmus (OKAN) is prominent in the monkey and persists for about 45–60 sec after the lights have been extinguished It is marked by the arrows in Fig 8 A B The direction of OKAN is the same as that of the OKN which preceded it

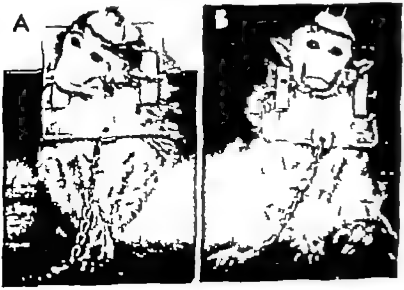

Fig 6 A Postural changes in Monkey 729 after left labyrinthectomy The head was tilted to the left. B After right labyrinthectomy the animal's head was still tilted slightly to the left side

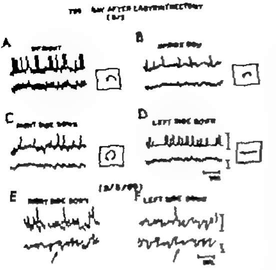

Fig. 7. A–D. Spontaneous and positional nystagmus one day after left labyrinthectomy in 729. The upper trace in each pair is the vertical EOG and the lower trace the horizontal EOG. The direction of the quick phases of nystagmus is shown in the diagram on the right. A, When the animal was upright, there was horizontal counter-clockwise rotatory spontaneous nystagmus to the contralateral side. C With the right side down the nystagmus was predominantly rotatory and D with the left side down it was predominantly horizontal. B Counter-clockwise rotatory nystagmus was also found in the upside down position. E, F Positional nystagmus 3 days after left labyrinthectomy in 729. With the right side or left side down, there was horizontal component to the *(left)* ipsilateral side. This is indicated by the arrows below the bottom traces. The vertical bars show the calibration which is 10° for both the horizontal and vertical EOGs.

After labyrinthectomy ipsilateral OKAN initially disappeared and contralateral OKAN was decreased. For example the duration of OKAN was 44 sec to the right and left in 707 before right labyrinthectomy (Fig. 8 A, B). Four days after labyrinthectomy there was no OKAN to the ipsilateral side and only 13 sec of OKAN to the contralateral side. Six days after operation the duration of OKAN was 3 sec to the ipsilateral (Fig. 8 C) and 18 sec to the contralateral side (Fig. 8 D). Findings were similar in 729.

Alcohol (1.5 g/kg) induced positional alcohol nystagmus (PAN) to both sides after labyrinthectomy (Fig. 9 D–F). The nystagmus was stronger to the contralateral side (Fig. 9 F). However if the intensity of the spontaneous nystagmus (Fig. 9 E) was added to the PAN of Fig. 9 D and subtracted from the PAN of Fig. 9 F then there was a relatively symmetrical effect of head position. This is shown by the graph of PAN after labyrinthectomy in Fig. 10 (solid lines). In both monkeys the magnitude of changes in PAN was about half that of the original effect before labyrinthectomy.

B. Bilateral labyrinthectomy. The second labyrinthectomy did not cause an ipsilateral head tilt in either monkey. That is the head still remained slightly tilted to the side of the first labyrinthectomy (Fig. 6 B). There was some difficulty in holding the head upright, but no definite falling tendency to either side. Contralateral spontaneous nystagmus was present for 2 days in light and for about 1 week in darkness. Spontaneous nystagmus was not affected by changes in head position before or after administration of alcohol (Fig. 9 G–I) but alcohol gaze nystagmus was still present.

OKN was initially somewhat asymmetrical after bilateral labyrinthectomy. There was a decrease in the velocity of slow phases of ipsilateral OKN. Moreover the animals could not follow well for OKN drum velocities above 60°/sec to either side for long periods of time (Cohen et al. 1973). OKAN could not be induced after bilateral labyrinthectomy in either animal, although OKN was present (Fig. 8 E, F). The loss of OKAN after bilateral labyrinthectomy was permanent (Fig. 8 G, H).

Comment

Signs after labyrinthectomy are similar to those reported previously (Magnus 1924, Northington & Barrera, 1934, Dow 1938). These included a head tilt and falling tendency toward the operated side, a tendency to circle in that direction and spontaneous nystagmus toward the opposite side. Recovery of postural asymmetry after unilateral labyrinthectomy

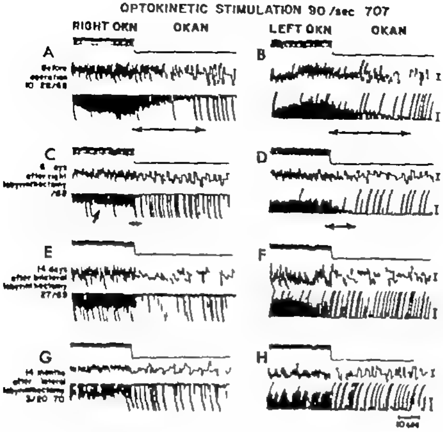

Fig 8 OKN and OKAN before operation (A B) after right labyrinthectomy (C D), and after bilateral labyrinthectomy (E–H) The upper trace in each part records the passage of drum stripes during OKN At the end of stimulation the lights were extinguished and the animal was in darkness for the remainder of the tracing The second trace is the horizontal EOG The third trace shows slow phase velocity The duration of OKAN is marked in A–D C D After right labyrinthectomy the monkey had OKN to both sides but there was a re tion in the maximum velocity of slow phases of O to the right (upward arrow). Note that OKAN markedly diminished after labyrinthectomy E–F After bilateral labyrinthectomy no OKAN recorded G H Similar findings were recorde months later The calibrations are 16° for the and 32°/sec for the slow phase velocity traces.

was almost complete within 1 month The second labyrinthectomy affected posture much less than the first operation

Spontaneous nystagmus was found in darkness for long periods after unilateral labyrinthectomy The small but clear-cut ipsilateral horizontal component found in the EOG at some time during the recovery course was also present in other animals when labyrinthectomy was done after vestibular nuclei lesions

The interaction between the vestibular and visual systems is seen in the effects of labyrinthectomy on OKN and OKAN Not only was there directional preponderance of OKN to the contralateral side after labyrinthectomy but the animals were unable to follow the OKN drum well to the either sid higher velocities Moreover OKAN markedly diminished after unilateral la rinthectomy and permanently lost after lateral labyrinthectomy This suggests that peripheral labyrinths and the vestibu system play an important role in support production of certain visual-ocular reflex

PAN is permanently abolished after lateral destruction of the labyrinths (deKle & Versteegh 1930 Aschan et al 196 However alcohol gaze nystagmus (Asch et al 1956) persists even after bilater labyrinthectomy (Harris et al 1962)

There is disagreement as to whether or n PAN is present to both sides after unilater labyrinthectomy In acute experiments it wa

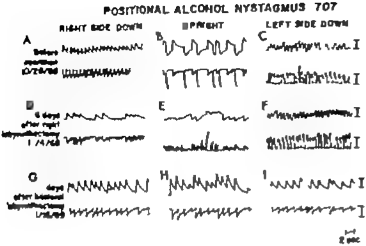

Fig 9 Positional alcohol nystagmus and labyrinthectomy in 707 The upper trace is the horizontal EOG and the lower trace the slow phase velocity Before operation there was active nystagmus t the right ith the right side down (A) and to the left with th the left side dow (C) Six days after right labyrinthectomy there was spontaneous nystagmus to the left in the upright position (E). Weak positional nystagmus was induced to the right i the right side down position (D) and strong positional nystagmus to the left in the left side down position (F). Four days after left (bilateral) labyrinthectomy there was spontaneous nystagmus to the right (H) which was unchanged in either right side down (G) or left side down (I) positions. The vertical bars beside the EOGs show the calibration which is 16° for the horizontal EOG and 32°/sec for the slow phase velocity traces.

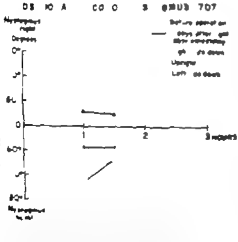

Fig 10 Graph of intensity of PAN I in 707 before (→) and after (←→) right labyrinthectomy Before labyrinthectomy the magnitude of the response was symmetrical to both sides After labyrinthectomy there as spontaneous nystagmus during hich the eye deviated about 150° to the left during 20 seconds. The magnitude of the change in the spontaneous nystagmus as approximately symmetrical during PAN

not present when the operated side was down (deKleijn & Versteegh 1930) However Aschan et al (1964) demonstrated it in a human subject 10 years after removal of a neurinoma with destruction of the vestibular nerve PAN I was present in monkeys in both directions after unilateral labyrinthectomy

The magnitude of PAN determined by adding the nystagmic responses in the right and left side down position before operation was decreased to about half after unilateral labyrinthectomy It would appear that the otolith organs on each side sense gravitational forces or linear acceleration almost equally in both directions and that about half of the ocular response is caused by each of them The semicircular canals also sense angular acceleration equally well in either direction after unilateral labyrinthectomy and the intensity of the ocular response to rotation is reduced by about half (Niven & Graybiel 1953 Money & Scott 1962)

4 Lesion of the Root Entry Zone

The left vestibular nerve was partially destroyed at the ventrolateral border of the LVN in Monkey 728 Diagrams through the lesion are shown in Fig 11 The lesion was about 2 5 mm long and 1 mm wide It lay in the middle portion of the vestibular nerve (Fig 11 B–D) and grazed the rostral end of DVN (Fig 11 D–F) As shown in Fig 11 C and Fig 12 there was demyelination and gliosis extending throughout the ventro-medial portion of LVN (smaller cell area) There was also some fiber loss in the most rostral portions of DVN (Fig 11 E) No significant gliosis was present in other parts of DVN in SVN or in the dorso-lateral portion (giant cell area) of LVN

Stimulation through the implanted electrode prior to lesion produced horizontal clockwise rotatory movements of the eyes to the ipsilateral side (⌒) The quick phases of nystagmus induced by repetitive stimulation were in the same direction as eye movements

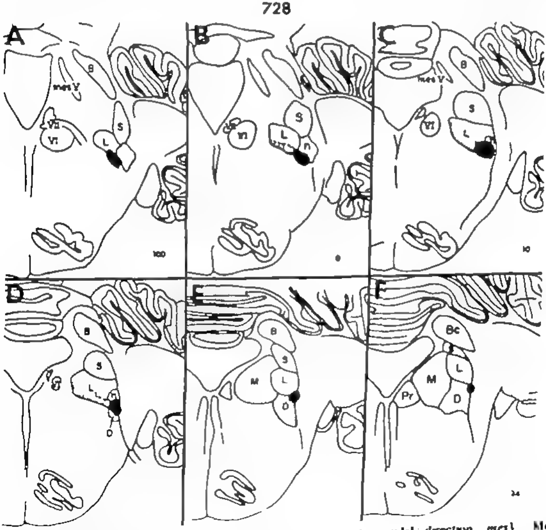

Fig 11 Diagram showing the lesion (black) and area of demyelination and gliosis (stippled) in 728 The sections which are shown extend over about 1.5 mm in the rostro-caudal direction *mes V* Mesencephalic trigeminal nucleus *Pr* Nucleus praepositus hypoglossi

Fig 12 Microphotographs of Section C Figure 11 showing the demyelination (A) and gliosis (B) i ventral portions of LVN after destruction of portion of the vestibular nerve root. The degeneration did not extend into the rostrodorsal (giant cell) area of LVN

induced by stimulation of this region with pulse trains After lesion there was a persistent head tilt (Fig 13 A) and a tendency to fall to the ipsilateral side The head tilt and falling tendency were somewhat stronger than in monkeys with unilateral labyrinthectomy (Fig. 6 A)

Spontaneous and positional nystagmus The spontaneous nystagmus was initially contralateral with a small counterclockwise rotatory component (Fig. 14 A). It was opposite in direction to the nystagmus induced by repetitive stimulation before lesion It persisted for 3 days in light and for 1 week in darkness

Lateral head positions were effective in inducing nystagmus throughout the animal's recovery course Initially contralateral counter clockwise rotatory nystagmus was induced when the opposite side was down (Fig 14 C) Later this nystagmus disappeared but there was downward nystagmus when the ipsilateral (left) side was down.

OKN and OKAN OKN and OKAN were symmetrical in this animal before lesion. Six days after lesion there was directional

Fig 13 A, Postural changes after nerve root lesion on left in 728 and B after contralateral (right) labyrinthectomy

4 Lesion of the Root Entry Zone

The left vestibular nerve was partially de stroyed at the ventrolateral border of the LVN in Monkey 728 Diagrams through the lesion are shown in Fig 11 The lesion was about 2 5 mm long and 1 mm wide It lay in the middle portion of the vestibular nerve (Fig 11 B–D) and grazed the rostral end of DVN (Fig 11 D–F) As shown in Fig 11 C and Fig 12 there was demyelination and gliosis extending throughout the ventro-medial por *tion of LVN (smaller cell area) There was* also some fiber loss in the most rostral por tions of DVN (Fig 11 E) No significant gliosis was present in other parts of DVN in SVN or in the dorso-lateral portion (giant cell area) of LVN

Stimulation through the implanted electrode prior to lesion produced horizontal clockwise rotatory movements of the eyes to the ipsi lateral side (⌒) The quick phases of nystagmus induced by repetitive stimulation *were in the same direction as eye movements*

728

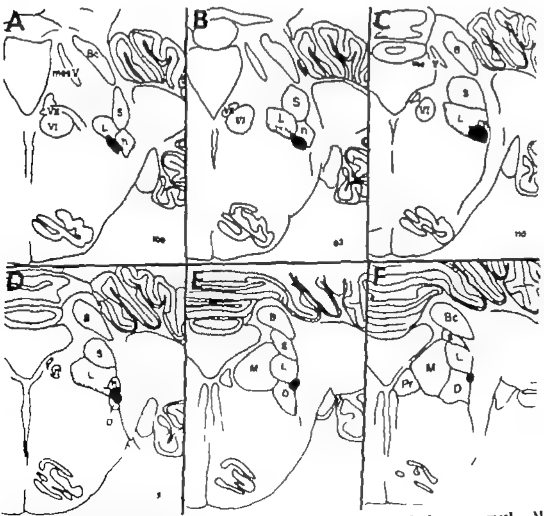

Fig 11 Diagram showing the lesion (black) and area of demyelination and gliosis (stippled) in 728 The sec tions which are shown extend over about 1.5 mm in the rostro-caudal direction *mesV* Mesencephalic trige minal nucleus *Pr* Nucleus praepositus hypoglossi

Fig. 12. Microphotographs of Section C, Figure 11 showing the demyelination (A) and gliosis (B) in ventral portions of LVN after destruction of portion of the vestibular nerve root. The degeneration did not extend into the rostrodorsal (giant cell) area of LVN

induced by stimulation of this region with pulse trains. After lesion there was a persistent head tilt (Fig. 13 A) and a tendency to fall to the ipsilateral side. The head tilt and falling tendency were somewhat stronger than in monkeys with unilateral labyrinthectomy (Fig. 6 A).

Spontaneous and positional nystagmus. The spontaneous nystagmus was initially contralateral with a small counterclockwise rotatory component (Fig. 14 A). It was opposite in direction to the nystagmus induced by repetitive stimulation before lesion. It persisted for 3 days in light and for 1 week in darkness.

Lateral head positions were effective in inducing nystagmus throughout the animal's recovery course. Initially contralateral counterclockwise rotatory nystagmus was induced when the opposite side was down (Fig. 14 C). Later this nystagmus disappeared but there was downward nystagmus when the ipsilateral (left) side was down.

OKN and OKAN. OKN and OKAN were symmetrical in this animal before lesion. Six days after lesion there was directional

Fig. 13. A, Postural changes after nerve root lesion on left in 728, and B, after contralateral (right) labyrinthectomy

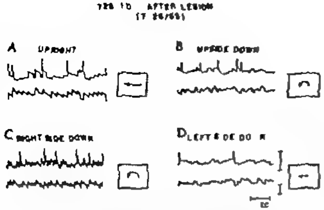

Fig 14 A–D Spontaneous and positional nystagmus in 728 one day after lesion The direction of the nystagmus is shown by the arrows beside the EOGs A When the animal was upright there was spontaneous horizontal nystagmus to the right. In right-side down (C) and upside down (B) positions the nystagmus was horizontal rotatory and in left-side down position (D), it was predominantly horizontal The upper trace in each pair is the vertical EOG and the lower trace the horizontal EOG The calibrations show 25° for both horizontal and vertical traces.

preponderance of OKN to the contralateral side This had almost disappeared by 14 days and by 40 days OKN was symmetrical OKAN was initially absent to the ipsilateral side and reduced to the contralateral side after lesion 40 days after the lesion the contra lateral OKAN had recovered but the ipsi lateral OKAN was still reduced

Caloric nystagmus The caloric response of the left ear was reduced after the lesion in 728 The defect was most apparent when water temperatures farther away from body temperature were used for stimulation For example when the right ear was stimulated 2 weeks after lesion there was a normal graded increase in maximum slow phase velocity dependent on the intensity of the stimu lus (Fig 15 right ear Fig 16 A solid lines) Stimulation of the left ear however induced nystagmus in whose maximum slow phase velocity did not increase along with increases in water temperature (Fig 15 left ear Fig 16 A dotted lines) Thus there was little or no recruitment when the intensity of the stimulus was increased Moreover the absolute value of the slow phase velocities induced at 27° and 17°C were lower after than before operation

The difference in the velocity of the slow phases of nystagmus induced by stimulation 10° above and below body temperature are marked in Fig 16 A by arrows There was a greater difference in the slow phase velocities induced by hot than by cold caloric stimula tion These findings are consistent with the interpretation that there was canal paresis on the left (lesion) side and directional pre ponderance of caloric nystagmus to the right An interesting feature of this nystagmus was that duration and maximum slow phase ve locity were affected differently There was little difference between the duration of ipsi- and contralateral caloric responses (Fig 16 B) although there was a distinct difference in the velocity of the slow phases (Fig 16 A)

PAN Monkey 728 was tested for PAN 15 days after lesion No spontaneous nystagmus was induced by alcohol and the animal had direction-changing positional nystagmus during *PAN I* The intensity of the nystagmus was somewhat greater to the right than to the left This probably reflected the right directional preponderance which was also pre sent in caloric nystagmus and OKN

Right labyrinthectomy After right labyrinthectomy there was a slight head tilt and a weak falling tendency to the right (Fig 13 B) For a short period after right labyrinthectomy there was spontaneous nystagmus to the left in light This nystagmus was much more intense with the left side down It was present in darkness one week later At that time the spontaneous nystagmus had an ipsilateral horizontal component in the EOG similar to that found after unilateral laby rinthectomy at a similar time after lesion (Fig 7 E F)

7 and 22 days after right labyrinthectomy slow phases of OKN were of greater velocity when OKN was to the left than to the right OKAN was initially absent to the right and reduced to the left when compared with

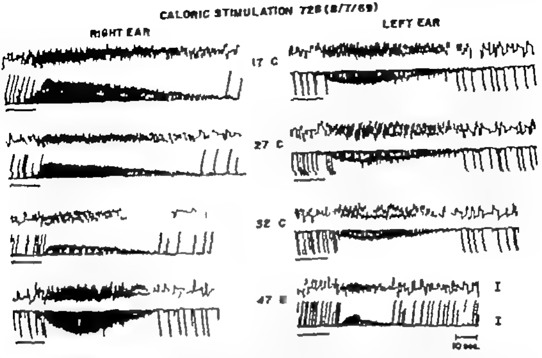

Fig. 15. Caloric nystagmus recorded 14 days after lesion in 728. The upper trace in each pair is the horizontal EOG and the lower trace shows slow phase velocity. The underlying horizontal bars show the duration of stimulation. At the end of stimulation the lights were extinguished and the rest of the recording was done in darkness. Notice that the nystagmus induced from the left ear by water temperatures of 17°C, 27°C, and 47°C was less intense than from the right ear. Nystagmus induced by water at 32°C was approximately symmetrical. The calibrations beside the lower right hand trace show 25° for the EOG and 50°/sec for the slow phase velocity trace.

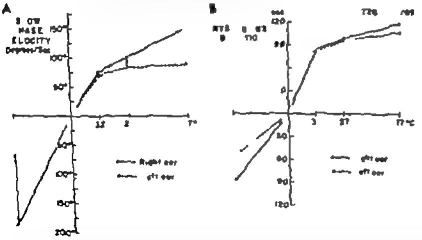

Fig. 16. Graphs of slow phase velocity (A) and duration (B) of the nystagmus shown in Fig. 15. Note the lower slow phase velocities induced by stimulation of the left ear (–). Note also the relatively limited increase in maximum slow phase velocity when water temperatures farther away from body temperature are used for stimulation of the left ear. There was not as much difference in duration of nystagmus induced from the two ears as in slow phase velocity. The arrows point to the differences in slow phase velocity which suggest directional preponderance to the right as well as canal paresis on the left.

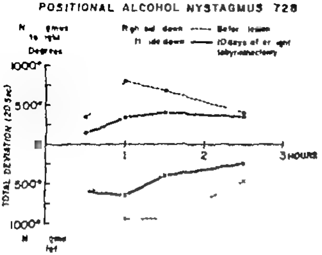

Fig 17 Total deviation during PAN I before lesion (- -) and 10 days after right labyrinthectomy (——)

OKAN recorded 40 days after the initial lesion Twenty two days after right labyrinthectomy the duration of OKAN was still shorter than before labyrinthectomy right> left

PAN was induced to both sides when tested 10 days after right labyrinthectomy (Fig 17 solid lines) The magnitude of the response during PAN was about half that of the original response (Fig 17 dotted lines)

Caloric nystagmus was induced by stimulation of the left ear 23 days after right labyrinthectomy The ipsilateral (left) nystagmus induced by stimulation with hot water (47°C) was now stronger than the contralateral (right) nystagmus induced by cold water (?7°C) Despite the reversal of directional preponderance of caloric nystagmus produced by the labyrinthectomy there was still no recruitment in the maximum velocity of slow phases by increasing the intensity of stimulation

Comment

The only gross changes in the vestibular nuclei in 728 were damage to the nerve root and gliosis and fiber loss in the ventral portion of LVN The latter finding was presumably secondary to interruption of the afferent fibers from the labyrinth Findings in 728 were similar to those in animals with unilateral labyrinthectomy (707 729) (1) head tilt and falling tendency to the ipsilateral side (2) spontaneous nystagmus toward the contralateral intact side (3) an effect of head position on spontaneous nystagmus (enhancement of the rotatory component with the intact side down) and (4) decreased or absent response to caloric testing i e canal paresis on the side of the lesion One exception was that the postural asymmetry was somewhat stronger after the nerve root (728) than the peripheral labyrinthine lesions (707 & 729) It appeared that the symptoms in 728 were mainly due to damage of the vestibular nerve trunk at the root entry zone

Responses from both the semicircular canals and otolith organs were affected by the lesion in 728 since there were changes in caloric nystagmus and some positional effects on the spontaneous nystagmus However the most striking changes were in caloric nystagmus and consisted of a decrease in the velocity of slow phases induced by stimulation of the ipsilateral ear and an inability of stronger caloric stimuli on the left to recruit stronger nystagmus Positional alcohol nystagmus was not much affected by the root entry zone lesion in 728 After the contralateral labyrinth was destroyed the magnitude of PAN was reduced to about half This is similar to changes in PAN in 707 and 729 after unilateral labyrinthectomy From this we would infer that the root entry zone lesion in 728 had not significantly interrupted primary afferents most probably from the otolith organs which produce PAN

5 Lesion of Rostral Descending Vestibular Nucleus

In 717 the main portion of the lesion was in rostral DVN on the right side (Fig. 18 E F I). Diagrams and microphotographs of the lesion in Figs. 18 and 19 were reversed to be compatible with those in other animals. The postural and EOG findings were not reversed, but are shown as recorded. The lesion also damaged the caudal portion of the nerve root (Fig. 18 C) and the lateral and ventral-most portions of LVN (Fig. 18 C–E, 19 B, C). Rostral-most parts of LVN remained intact (Fig. 18 A). In rostral LVN gliosis and fiber loss were limited to the ventral portions (Fig. 18 B) but were present in both ventral and dorsal portions of caudal LVN (Fig. 18 C, D). Gliosis and fiber loss extended throughout DVN caudal to the lesion (Fig. 18 G, H). The demyelination in caudal DVN on the lesion side can be seen by comparing it to DVN on the normal side (Fig. 19 D, arrows). In the cerebellum there was gliosis and loss of myelinated fibers in the medial part of the ipsilateral fastigial nucleus (Fig. 18 E–H). MVN and SVN were not affected.

Stimulation with pulse trains through the implanted electrodes before lesion caused the eyes to move to the ipsilateral side (←). Horizontal rotatory nystagmus to the ipsilateral side was induced by repetitive stimulation (↶). After the lesion there was a strong head tilt and falling tendency to the ipsilateral side (Fig. 20 A) and some head

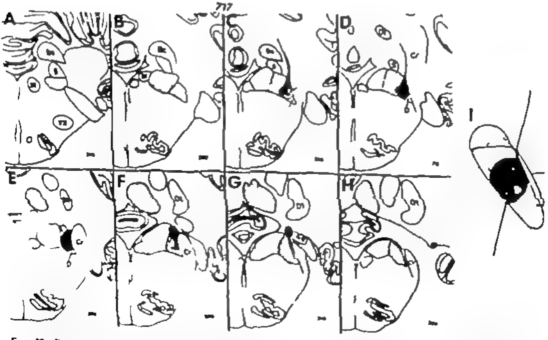

Fig. 18. Diagrams of lesion (black) and areas of demyelination and gliosis (stippled) in 717. The extent of the lesion and of the degenerative changes are shown in I which is a sagittal view of the vestibular nuclei from the lateral side. The vertical line shows the plane of section for A–H and for Fig. 19. *Cr* Restiform body. *chl N* Cochlear nerve.

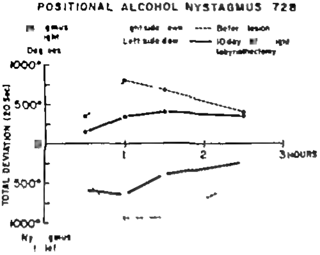

Fig 17 Total deviation during PAN I before lesion (- - -) and 10 days after right labyrinthectomy (——).

OKAN recorded 40 days after the initial lesion Twenty two days after right labyrinthectomy the duration of OKAN was still shorter than before labyrinthectomy right> left

PAN was induced to both sides when tested 10 days after right labyrinthectomy (Fig 17 solid lines) The magnitude of the response during PAN was about half that of the original response (Fig 17 dotted lines)

Caloric nystagmus was induced by stimulation of the left ear 23 days after right labyrinthectomy The ipsilateral (left) nystagmus induced by stimulation with hot water (47°C) was now stronger than the contralateral (right) nystagmus induced by cold water (27°C) Despite the reversal of directional preponderance of caloric nystagmus produced by the labyrinthectomy there was still no recruitment in the maximum velocity of slow phases by increasing the intensity of stimulation

Comment

The only gross changes in the vestibular nuclei in 728 were damage to the nerve root and gliosis and fiber loss in the ventral portion of LVN The latter finding was presumably secondary to interruption of the afferent fibers from the labyrinth Findings in 728 were similar to those in animals with unilateral labyrinthectomy (707 729) (1) head tilt and falling tendency to the ipsilateral side (2) spontaneous nystagmus toward the contralateral intact side (3) an effect of head position on spontaneous nystagmus (enhancement of the rotatory component with the intact side down) and (4) decreased or absent response to caloric testing i e canal paresis on the side of the lesion One exception was that the postural asymmetry was somewhat stronger after the nerve root (728) than the peripheral labyrinthine lesions (707 & 729) It appeared that the symptoms in 728 were mainly due to damage of the vestibular nerve trunk at the root entry zone

Responses from both the semicircular canals and otolith organs were affected by the lesion in 728 since there were changes in caloric nystagmus and some positional effects on the spontaneous nystagmus However the most striking changes were in caloric nystagmus and consisted of a decrease in the velocity of slow phases induced by stimulation of the ipsilateral ear and an inability of stronger caloric stimuli on the left to recruit stronger nystagmus Positional alcohol nystagmus was not much affected by the root entry zone lesion in 728 After the contralateral labyrinth was destroyed the magnitude of PAN was reduced to about half This is similar to changes in PAN in 707 and 729 after unilateral labyrinthectomy From this we would infer that the root entry zone lesion in 728 had not significantly interrupted primary afferents most probably from the otolith organs *which produce PAN*

5 Lesion of Rostral Descending Vestibular Nucleus

In 717 the main portion of the lesion was in rostral DVN on the right side (Fig 18 E F I) Diagrams and microphotographs of the lesion in Figs 18 and 19 were reversed to be compatible with those in other animals The postural and EOG findings were not reversed, but are shown as recorded. The lesion also damaged the caudal portion of the nerve root (Fig. 18 C) and the lateral and ventral-most portions of LVN (Fig 18 C–E 19 B C) Rostral-most parts of LVN remained intact (Fig. 18 A) In rostral LVN gliosis and fiber loss were limited to the ventral portions (Fig. 18 B) but were present in both ventral and dorsal portions of caudal LVN (Fig. 18 C D) Gliosis and fiber loss extended throughout DVN caudal to the lesion (Fig 18 G H) The demyelination in caudal DVN on the lesion side can be seen by comparing it to DVN on the normal side (Fig 19 D arrows) In the cerebellum there was gliosis and loss of myelinated fibers in the medial part of the ipsilateral fastigial nucleus (Fig. 18 E–H) MVN and SVN were not affected.

Stimulation with pulse trains through the implanted electrodes before lesion caused the eyes to move to the ipsilateral side (←) Horizontal rotatory nystagmus to the ipsilateral side was induced by repetitive stimulation (↶) After the lesion there was a strong head tilt and falling tendency to the ipsilateral side (Fig. 20 A) and some head

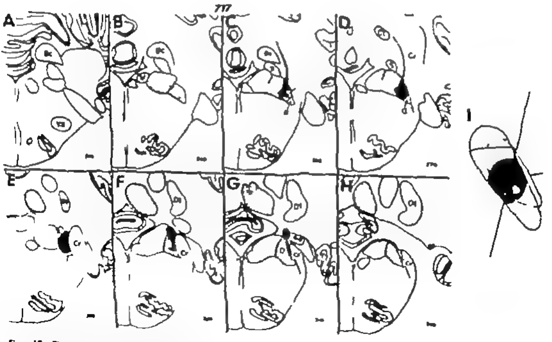

Fig 18 Diagrams of lesion (black) and areas of demyelination and gliosis (stippled) in 717 The extent of the lesion and of the degenerative changes are shown in I black in sagittal view of the vestibular nuclei from the lateral side. The vertical line shows the plane of section for A–H and for Fig. 19 C Restiform body *cN* Cochlear nerve.

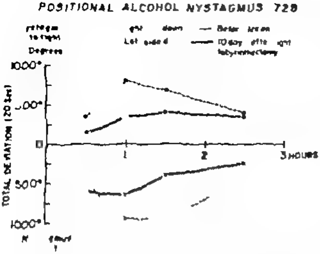

Fig 17 Total deviation during PAN I before lesion (- - -) and 10 days after right labyrinthectomy (——)

OKAN recorded 40 days after the initial lesion Twenty two days after right labyrinthectomy the duration of OKAN was still shorter than before labyrinthectomy right> left

PAN was induced to both sides when tested 10 days after right labyrinthectomy (Fig 17 solid lines) The magnitude of the response during PAN was about half that of the original response (Fig 17 dotted lines)

Caloric nystagmus was induced by stimulation of the left ear 23 days after right labyrinthectomy The ipsilateral (left) nystagmus induced by stimulation with hot water (47°C) was now stronger than the contralateral (right) nystagmus induced by cold water (27°C) Despite the reversal of directional preponderance of caloric nystagmus produced by the labyrinthectomy there was still no recruitment in the maximum velocity of slow phases by increasing the intensity of stimulation

Comment

The only gross changes in the vestibular nuclei in 728 were damage to the nerve root and gliosis and fiber loss in the ventral portion of LVN The latter finding was presumably secondary to interruption of the afferent fibers from the labyrinth Findings in 728 were similar to those in animals with unilateral labyrinthectomy (707 729): (1) head tilt and falling tendency to the ipsilateral side (2) spontaneous nystagmus toward the contralateral intact side (3) an effect of head position on spontaneous nystagmus (enhancement of the rotatory component with the intact side down) and (4) decreased or absent response to caloric testing i e canal paresis on the side of the lesion One exception was that the postural asymmetry was somewhat stronger after the nerve root (728) than the peripheral labyrinthine lesions (707 & 729) It appeared that the symptoms in 728 were mainly due to damage of the vestibular nerve trunk at the root entry zone

Responses from both the semicircular canals and otolith organs were affected by the lesion in 728 since there were changes in caloric nystagmus and some positional effects on the spontaneous nystagmus However the most striking changes were in caloric nystagmus and consisted of a decrease in the velocity of slow phases induced by stimulation of the ipsilateral ear and an inability of stronger caloric stimuli on the left to recruit stronger nystagmus Positional alcohol nystagmus was not much affected by the root entry zone lesion in 728 After the contralateral labyrinth was destroyed the magnitude of PAN was reduced to about half This is similar to changes in PAN in 707 and 729 after unilateral labyrinthectomy From this we would infer that the root entry zone lesion in 728 had not significantly interrupted primary afferents most probably from the otolith organs which produce PAN

5 Lesion of Rostral Descending Vestibular Nucleus

In 717 the main portion of the lesion was in rostral DVN on the right side (Fig 18 E F I) Diagrams and microphotographs of the lesion in Figs. 18 and 19 were reversed to be compatible with those in other animals The postural and FOG findings were not reversed but are shown as recorded The lesion also damaged the caudal portion of the nerve root (Fig. 18 C) and the lateral and ventral-most portions of LVN (Fig. 18 C–E 19 B C) Rostral-most parts of LVN remained intact (Fig. 18 A) In rostral LVN gliosis and fiber loss were limited to the ventral portions (Fig. 18 B) but were present in both ventral and dorsal portions of caudal LVN (Fig. 18 C D) Gliosis and fiber loss extended throughout DVN caudal to the lesion (Fig 18 G H) The demyelination in caudal DVN on the lesion side can be seen by comparing it to DVN on the normal side (Fig 19 D arrows) In the cerebellum there was gliosis and loss of myelinated fibers in the medial part of the ipsilateral fastigial nucleus (Fig. 18 E–H) MVN and SVN were not affected.

Stimulation with pulse trains through the implanted electrodes before lesion caused the eyes to move to the ipsilateral side (←) Horizontal rotatory nystagmus to the ipsilateral side was induced by repetitive stimulation (⌒) After the lesion there was a strong head tilt and falling tendency to the ipsilateral side (Fig 20 A) and some head

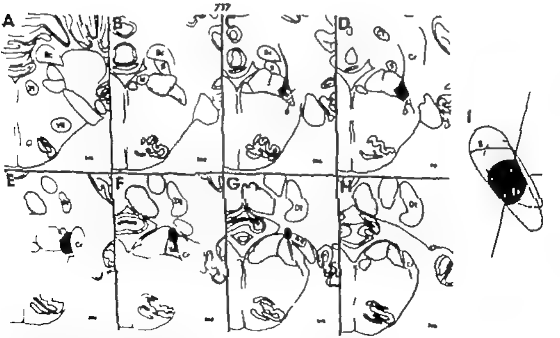

Fig 18 Diagrams of lesion (black) and areas of demyelination and gliosis (stippled) in 717 The extent of the lesion and of the degenerative changes are shown in I which is sagittal view of the vestibular nuclei from the lateral side. The vertical line shows the plane of section for A–H and for Fig. 19 C Restiform body· *cld N* Cochlear nerve.

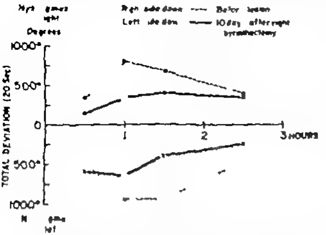

Fig 17 Total deviation during PAN I before lesion (- - -) and 10 days after right labyrinthectomy (——)

OKAN recorded 40 days after the initial lesion Twenty two days after right labyrinthectomy the duration of OKAN was still shorter than before labyrinthectomy right> left

PAN was induced to both sides when tested 10 days after right labyrinthectomy (Fig 17 solid lines) The magnitude of the response during PAN was about half that of the original response (Fig 17 dotted lines)

Caloric nystagmus was induced by stimulation of the left ear 23 days after right labyrinthectomy The ipsilateral (left) nystagmus induced by stimulation with hot water (47°C) was now stronger than the contralateral (right) nystagmus induced by cold water (27°C) Despite the reversal of directional preponderance of caloric nystagmus produced by the labyrinthectomy there was still no recruitment in the maximum velocity of slow phases by increasing the intensity of stimulation

Comment

The only gross changes in the vestibular nuclei in 728 were damage to the nerve root and ghosis and fiber loss in the ventral portion of LVN The latter finding was presumably secondary to interruption of the afferent fibers from the labyrinth Findings in 728 were similar to those in animals with unilateral labyrinthectomy (707 729) (1) head tilt and falling tendency to the ipsilateral side (2) spontaneous nystagmus toward the contralateral intact side (3) an effect of head position on spontaneous nystagmus (enhancement of the rotatory component with the intact side down) and (4) decreased or absent response to caloric testing i e canal paresis on the side of the lesion One exception was that the postural asymmetry was somewhat stronger after the nerve root (728) than the peripheral labyrinthine lesions (707 & 729) It appeared that the symptoms in 728 were mainly due to damage of the vestibular nerve trunk at the root entry zone

Responses from both the semicircular canals and otolith organs were affected by the lesion in 728 since there were changes in caloric nystagmus and some positional effects on the spontaneous nystagmus However the most striking changes were in caloric nystagmus and consisted of a decrease in the velocity of slow phases induced by stimulation of the ipsilateral ear and an inability of stronger caloric stimuli on the left to recruit stronger nystagmus Positional alcohol nystagmus was not much affected by the root entry zone lesion in 728 After the contralateral labyrinth was destroyed the magnitude of PAN was reduced to about half This is similar to changes in PAN in 707 and 729 after unilateral labyrinthectomy From this we would infer that the root entry zone lesion in 728 had not significantly interrupted primary afferents most probably from the otolith organs which produce PAN

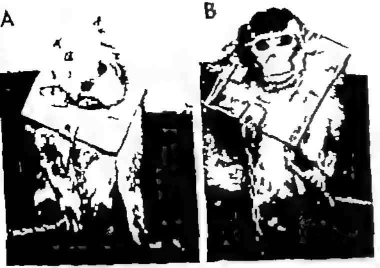

Fig. 20. A. Head tilt to the ipsilateral (right) side after right DVN lesion in 717. The monkey also had some falling tendency to the right. B. Head and body posture after left labyrinthectomy.

22, 23 A, dotted lines). There was no difference in velocity of slow phases of nystagmus induced by hot stimulation of two ears (Fig. 22, 47°C; 23 A, arrows). Nystagmus duration was not of value in reflecting the side of the lesion in 717 since the duration of caloric nystagmus was longer after stimulation of the lesion side (Fig. 23 B, solid lines, right ear) than the intact side (Fig. 23 B, dotted lines, left ear).

PAN. Administration of alcohol on the 12th day after lesion provoked strong spontaneous nystagmus to the ipsilateral (right) side (Fig. 24 E, upright). Nystagmus to the right was enhanced when the ipsilateral (right) side was down (Fig. 24 D) and was inhibited when the contralateral (left) side was down (Fig. 24 F). On the 48th day there was also strong spontaneous nystagmus to the ipsilateral side (Fig. 24 H, upright). It was enhanced with the ipsilateral side down (Fig. 24 G) and reversed when the contralateral side was down (Fig. 24 I).

Left labyrinthectomy. The left labyrinth was destroyed 71 days after lesion. After labyrinthectomy there was a slight head tilt to the left with some falling tendency to the left (Fig. 20 B). There was spontaneous nystagmus to the right after labyrinthectomy. It was not affected by moving the head into either the right or left lateral position. On the 8th day after operation the spontaneous nystagmus was still present in darkness. Administration of alcohol enhanced the spontaneous nystagmus (Fig. 24 K), but neither the right (Fig. 24 J) nor the left lateral positions (Fig. 24 L) had any effect on this nystagmus.

Associated with the strong spontaneous

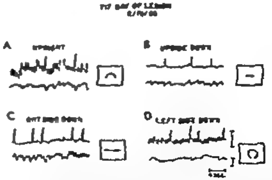

Fig. 21. Spontaneous (A) and positional nystagmus shortly after lesion in 717. A. There was strong spontaneous rotatory nystagmus to the left. The nystagmus was predominantly horizontal with the lesion side (*right*) down (C) or upside down (B). With the left side down (D) the nystagmus was rotatory. The vertical bars show 20° of deviation for the vertical (*upper trace*) and horizontal (*lower trace*) EOGs.

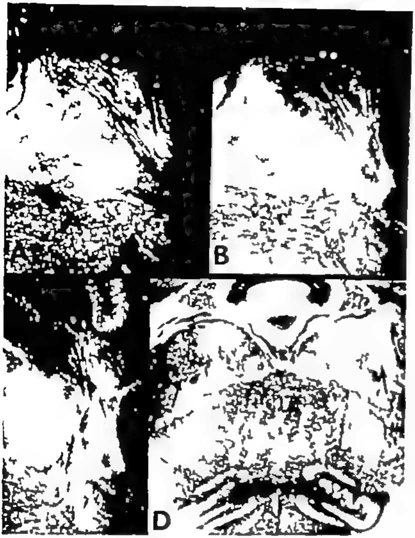

Fig 19 A–D Photomicrographs of destruction and demyelination in the vestibular nuclei in 717 Weil stain These sections correspond to or are close to the following diagrams in Fig. 18. A and Fig. 18 B B and Fig. 18 D C and Fig. 18 E and D and Fig. 18 G The arrows in D point to caudal DVN on both sides. Note the demyelination on the lesion side.

nystagmus The head tilt was more marked than that after labyrinthine destruction in 707 and 729 However the monkey was able to sit on the day of the lesion

Spontaneous and positional nystagmus Contralateral spontaneous nystagmus was present after lesion (Fig 21 A) It had strong clockwise rotatory and upward components and lasted for 8 days in light It was more persistent than in monkeys with unilateral labyrinthectomy 12 days later the horizontal component of the spontaneous nystagmus reversed

The effect of head position on the spontaneous nystagmus was similar to that after labyrinthectomy the horizontal component was enhanced when the ipsilateral side was down (Fig 21 C bottom trace) and the rotatory component was more prominent when the contralateral side was down (Fig 21 D) Later rotatory nystagmus appeared only when the contralateral (left) side was down

OKN and OKAN OKN was almost symmetrical to both sides by the 8th day after lesion OKAN was markedly diminished by the lesion ipsilateral>contralateral It had not recovered by 9 weeks after lesion

Caloric nystagmus Findings in 717 were similar to those in 728 in that more intense caloric nystagmus could not be recruited by applying stronger cold caloric stimuli to the ear on the side of the lesion Caloric nystagmus induced 2 months after lesion is shown in Fig 22 and analysed in Fig 23 The velocity of slow phases induced by cold stimulation was less from the right ear (Fig 22 23 A solid lines) than from the left ear (Fig

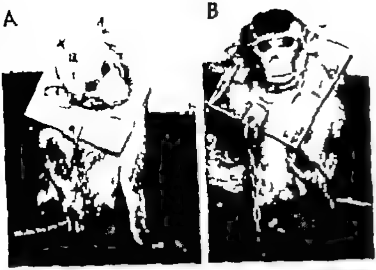

Fig. 20. A. Head tilt to the ipsilateral (right) side after right DVN lesion in 717. The monkey also had some falling tendency to the right. B. Head and body posture after left labyrinthectomy.

22, 23 A, dotted lines). There was no difference in velocity of slow phases of nystagmus induced by hot stimulation of two ears (Fig. 22, 47°C; 23 A, arrows). Nystagmus duration was not of value in reflecting the side of the lesion in 717 since the duration of caloric nystagmus was longer after stimulation of the lesion side (Fig. 23 B, solid lines, right ear) than the intact side (Fig. 23 B, dotted lines, left ear).

PAN. Administration of alcohol on the 12th day after lesion provoked strong spontaneous nystagmus to the ipsilateral (right) side (Fig. 24 E, upright). Nystagmus to the right was enhanced when the ipsilateral (right) side was down (Fig. 24 D) and was inhibited when the contralateral (left) side was down (Fig. 24 F). On the 48th day there was also strong spontaneous nystagmus to the ipsilateral side (Fig. 24 H, upright). It was enhanced with the ipsilateral side down (Fig. 24 G) and reversed when the contralateral side was down (Fig. 24 I).

Left labyrinthectomy. The left labyrinth was destroyed 71 days after lesion. After labyrinthectomy there was a slight head tilt to the left with some falling tendency to the left (Fig. 20 B). There was spontaneous nystagmus to the right after labyrinthectomy. It was not affected by moving the head into either the right or left lateral position. On the 8th day after operation the spontaneous nystagmus was still present in darkness. Administration of alcohol enhanced the spontaneous nystagmus (Fig. 24 K), but neither the right (Fig. 24 J) nor the left lateral positions (Fig. 24 L) had any effect on this nystagmus.

Associated with the strong spontaneous

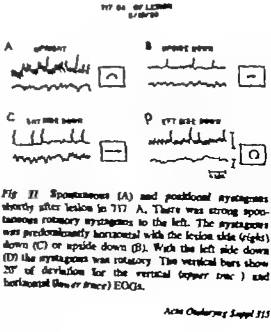

Fig. 21. Spontaneous (A) and positional nystagmus shortly after lesion in 717. A. There was strong spontaneous rotatory nystagmus to the left. The nystagmus was predominantly horizontal with the lesion side (right) down (C) or upside down (B). With the left side down (D) the nystagmus was rotatory. The vertical bars show 20° of deviation for the vertical (upper trace) and horizontal (lower trace) EOGs.

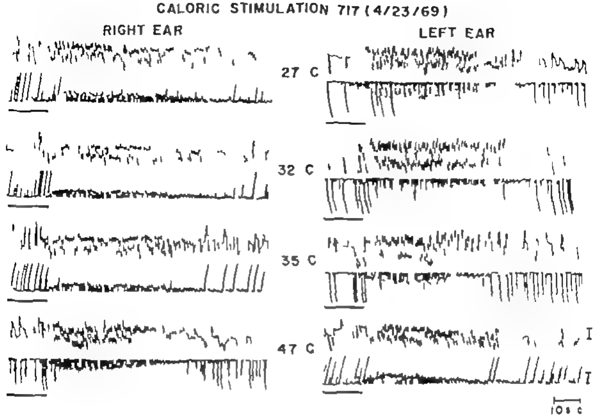

Fig 22 Nystagmus induced by caloric stimulation 2 months after lesion. The EOG is the upper trace and slow phase velocity is the lower trace The solid bars under the slow phase velocity trace show the duration of stimulation The lights were extinguished at the end of stimulation and the caloric nystagmus was recorded in darkness Note that the velocity of the slow phases induced by stimulating the right ear with cold water did not increase as the stimuli were made more intense The vertical bars are 70° for the horizontal EOG and 80°/sec for the slow phase velocity traces

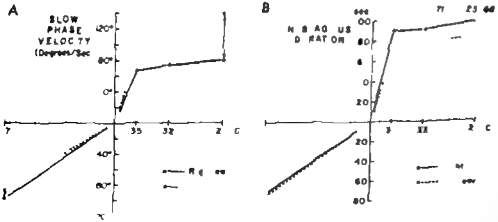

Fig 23 Graphs of slow phase velocity (A) and duration (B) of nystagmu induced by caloric stimulation 2 months after lesion 717 The lesion side is the right (—) and the intact side the left ( ) There was little increase in the maximum velocity of the slow phases when stimulating the ipsilateral ear nd more intense stimuli were unable to recruit faste slow phases *B Nystagmu induced by cold stimulation was of longer duration from the ipsilateral (right) side than* f m the contralateral side after lesion

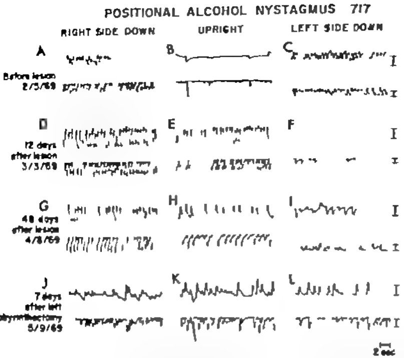

Fig. 24. Spontaneous alcohol nystagmus (upright) and positional alcohol nystagmus (right side down and left side down) before lesion (A–C), 12 and 48 days after lesion (D–I), and 7 days after contralateral labyrinthectomy (J–L). Note the strong spontaneous alcohol nystagmus to the right (ipsilateral side) after lesion (E). 48 days after lesion, however, it was possible to induce geotropic direction-changing PAN to both sides (G & I). After contralateral labyrinthectomy (J–L) there was no measurable effect of head position change on the spontaneous nystagmus after alcohol administration. The top trace in each pair is the horizontal EOG and the bottom trace shows slow phase velocity. The vertical bars are 20° for the EOG and 40°/sec for slow phase velocity.

nystagmus there was also strong directional preponderance of OKN and of caloric nystagmus to the right after left labyrinthectomy. However, it was still possible to induce contralateral and ipsilateral nystagmus by caloric stimulation of the ear on the lesion (right) side. Stronger (colder) caloric stimuli still failed to recruit slow phases of higher velocity as before lesion. OKAN could not be induced to the contralateral (left) side and was reduced in duration to the right.

Comment

The postural asymmetry and head tilt in 717 was more marked than in other monkeys, including those with unilateral labyrinthectomy. After the initial contralateral nystagmus had subsided there was persistent directional preponderance of nystagmus to the ipsilateral side. This preponderance was not produced by unilateral labyrinthectomy or by root entry zone lesion as in 728 and was most likely a result of the rostral DVN lesion.

The major findings in this animal were that after lesion and contralateral labyrinthectomy, head position had no effect on the spontaneous nystagmus and PAN could not be induced. This did not occur after lesions of other parts of the vestibular nuclei. It seems likely that the rostral DVN lesion in 717 had caused an interruption of otolith-ocular reflex arcs from the ipsilateral ear. The lesion in 717 did not involve the most lateral portion of rostral DVN (Fig. 18 C, D), where the main inflow from the utricle enters the vestibular nuclei (Stein & Carpenter, 1967). We would

infer therefore that it was the destruction of the primary receiving area for this activity in rostral DVN rather than damage to the nerve root which was responsible for the findings in 717

Primary afferents which project into ventral LVN were destroyed in 717 and 728 This probably accounts for the changes in slow phase velocity and loss of recruitment on stimulation of the ipsilateral ear in both animals The larger difference in the slow phas velocities induced by cold than by hot stimul in 717 (Fig. 23 A) than in 728 (Fig. 16 A was probably due to the presence of ipsila teral directional preponderance in 717 Th directional preponderance was probabl responsible for the nystagmus of longe duration to the lesion side (right) than t the contralateral side (Fig 23 B) in 717

6 Lesion of Caudal Descending Vestibular Nucleus

Central and caudal parts of left DVN were destroyed in 712 (Fig. 25 C–E 26) The rostral portion of DVN was intact (Fig. 25 A) There was slight involvement of caudal portions of MVN at the junction with DVN (Fig 25 B–D) Gliosis and fiber loss was extensive throughout portions of DVN which had not been destroyed (Fig. 25 D Fig. 26) The lesion did not involve the nerve roots and LVN The restiform body was intact and the cerebellar nuclei were normal

Stimulation through the implanted electrodes with pulse trains before the lesion caused ipsilateral (left) deviation of the eyes

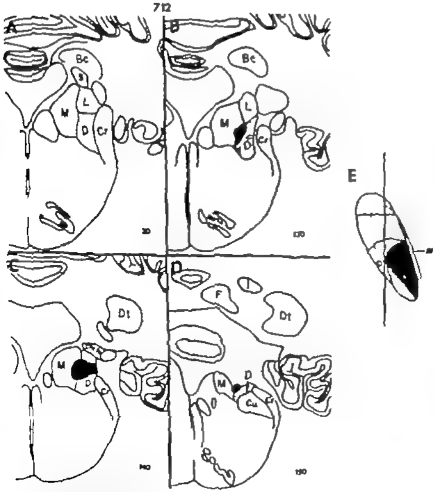

Fig 25 A–D Diagrams of lesion in Monkey 712. E. Extent of lesion in sagittal plane as seen from lateral aspect. The vertical line through E shows the plane of section for Figs 25 A–D and 26. C Cuneate nucleus.

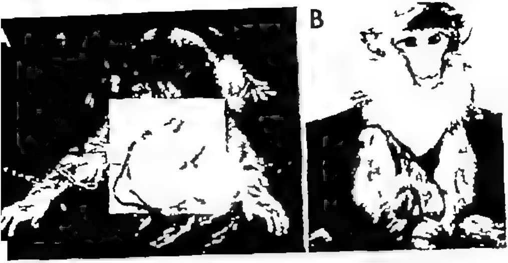
infer therefore that it was the destruction of the primary receiving area for this activity in rostral DVN rather than damage to the nerve root which was responsible for the findings in 717

Primary afferents which project into ventral LVN were destroyed in 717 and 728 This probably accounts for the changes in slow phase velocity and loss of recruitment on stimulation of the ipsilateral ear in both animals The larger difference in the slow pha velocities induced by cold than by hot stim in 717 (Fig. 23 A) than in 728 (Fig. 16 was probably due to the presence of ipsi teral directional preponderance in 717 Th directional preponderance was probal responsible for the nystagmus of lon duration to the lesion side (right) than the contralateral side (Fig 23 B) in 717



ig 27 A. Strong falling tendency and head tilt to
e left in 712 after left DVN lesion. B Head position
d body posture after right labyrinthectomy

he left was present days after operation but it had disappeared when the animal was tested 5 days later

Head position continued to affect nystagmus after labyrinthectomy When the right (labyrinthectomy) side was down the spontaneous nystagmus to the left was enhanced When the left side was down the spontaneous nystagmus was inhibited

OKN tested 24 days after operation was almost symmetrical (Fig. 29 G H) The duration of OKAN was diminished bilaterally right more than left (Fig. 29 G H) Geotropic direction-changing PAN was induced to both sides after right labyrinthectomy (Fig. 30 J L). The total magnitude of the response 7 days after operation was about half that of the initial reaction.

Comment

The ipsilateral falling tendency and head tilt were striking in this animal The difficulty in maintaining upright posture would indicate that DVN has a strong effect on spinal motor systems. Postural imbalance was stronger after the caudal DVN lesion than after lesion of other parts of the vestibular complex. In particular there was a strong effect on the trunk which suggests that caudal DVN may have a close relation to lumbar and hindlimb muscles

Changes in caloric nystagmus and OKN were not striking after the caudal DVN lesion. The contralateral spontaneous nystag

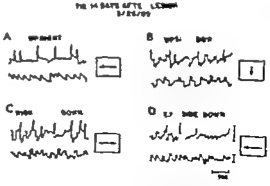


Fig 28 Spontaneous and positional nystagmus in Monkey 71... The vertical bars show 20° for the vertical (*upper trac*) and horizontal (*lower trac*) EOGs.

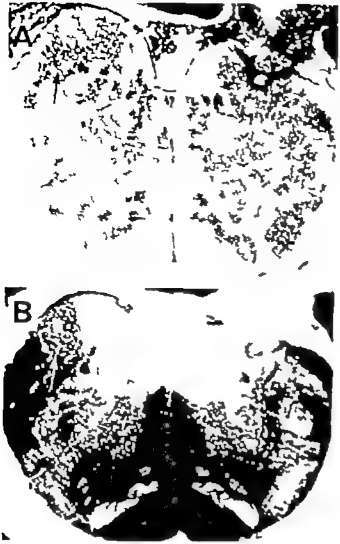

Fig 26 Cresyl violet (A) and Weil (B) stains showing the degeneration in DVN after lesion in 71 These sections were diagrammed in Fig. 25 D The atrophic DVN on the lesion (*left*) side can be compared to the normal DVN on the intact side (*arrow*).

with counterclockwise rotation ( ) Repetitive stimulation induced ipsilateral clockwise nystagmus ( )

After lesion the animal hade severe dysequilibrium and was not able to sit upright for 4 days (Fig 27 A) The chin was rotated to the contralateral side and the occiput to the ipsilateral side The dysequilibrium was much more severe in 712 than in animals with unilateral labyrinthectomy (707 & 729) root entry zone lesion (728) or destruction of rostral DVN (717) Each of these animals was able to sit shortly after lesion

Spontaneous and positional nystagm Spontaneous nystagmus was not presen this animal either in light or behind Fre glasses one day after lesion Later con lateral (right) spontaneous nystagmus present in darkness (Fig 28 A) This was only animal in whom apogeotropic directi changing positional nystagmus was promin after the lesion When the right side down the quick phases were directed to left (Fig 28 C) and when the left side down they were directed to the right (F 28 D) Upside down the nystagmus was dow ward (Fig 28 B) Both the spontaneous positional nystagmus were still present wh the animal was tested 30 days after lesi

OKN and OKAN OKN and OKAN w little affected by the DVN lesion (Fig C–F) 3 days after lesion OKAN was of lon duration to the contralateral side (F 29 C) but was present to the ipsilate side (Fig 29 D) It was more symmetri 10 days after lesion (Fig 29 E F)

Caloric nystagmus Caloric nystagm also was not much affected by destruction the central and caudal parts of DVN T nystagmus was somewhat stronger to t contralateral (right) than to the ipsilate (left) side This was the direction of t spontaneous nystagmus (Fig 28 A)

PAN Despite the apogeotropic dire tion-changing positional nystagmus produc by the lesion geotropic direction-changi positional nystagmus was induced after a ministration of alcohol during PAN I (Fi 30 D F G I) The intensity of the nysta mus 6 days after DVN destruction (Fi 30 D F) was less than before lesion (Fi 30 A C) 29 days after lesion the intensit of PAN had recovered to pre-operative te levels (Fig 30 G I)

Right labyrinthectomy Labyrinthectom was performed 70 days after the initial lesion After operation there was a slight head til to the right (Fig 27 B) There was no strik ing falling tendency to the right after laby rinthectomy Some spontaneous nystagmus to

mus in darkness may have been responsible for the slight contralateral directional preponderance of caloric nystagmus and OKN The findings suggest that caudal DVN is not much involved in processing information from the lateral semicircular canals

Apogeotropic direction-changing positional nystagmus was long lasting in this animal Similar positional nystagmus did not occur after lesions of other parts of the vestibular complex. This type of positional nystagmus has also been found after lesions of the cerebellar nuclei (Cohen et al 1969 Cohen & Highstein 1972) It is of interest in view of the close anatomical relationship between caudal DVN and the cerebellum (Brodal & Torvik, 1957 Carpenter 1960 Carpenter et al 1960 Angaut & Brodal 1967)

PAN I was induced 6 days after lesion (Fig. 30 D F) but was weaker than before lesion (Fig. 30 A C). The decrease in intensity may be explained by a subtraction of the apogeotropic direction-changing positional nystagmus due to the lesion from the geotropic PAN When the positional nystagmus decreased, the nystagmus of PAN I was stronger (Fig. 30 G I) PAN I was also induced after contralateral labyrinthectomy (Fig. 30 K L) This suggests that the lesion had not directly affected portions of the vestibular nuclei which process the incoming information responsible for PAN This is in contrast to the loss of PAN after destruction of rostral DVN in 717 Caudal DVN probably maintains an indirect or secondary influence on information arising in the otolith organs

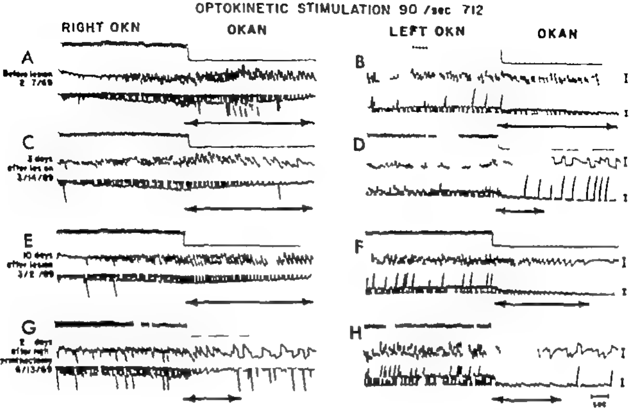

Fig 29 A–F OKN and OKAN before and after left DVN lesion and G H after contralateral (*right*) labyrinthectomy The top trace in each pair is a photocell recording showing passage of drum stripes The vertical bars show 70° for the horizontal EOG (*middle trace*) and 40°/sec for slow phase velocity (*bottom trace*)

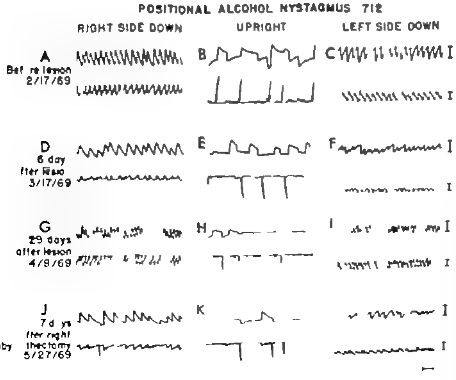

Fig 30 Positional alcohol nystagmus in 71 before (A C) and after (D F G I) left DVN lesion and after right labyrinthectomy (J L) Note that geotropic direction-changing PAN was present after lesion (D F G I) and after right labyrinthectomy (J L) The vertical bars show 70° for the horizontal EOG (*upper trace*) and 40°/sec for the slow phase velocity (*lower trace*)

mus in darkness may have been responsible for the slight contralateral directional pre ponderance of caloric nystagmus and OKN The findings suggest that caudal DVN is not much involved in processing information from the lateral semicircular canals

Apogeotropic direction-changing positional nystagmus was long lasting in this animal Similar positional nystagmus did not occur after lesions of other parts of the vestibular complex. This type of positional nystagmus has also been found after lesions of the cere bellar nuclei (Cohen et al 1969 Cohen & Highstein 1972) It is of interest in view of the close anatomical relationship between caudal DVN and the cerebellum (Brodal & Torvik 1957 Carpenter 1960 Carpenter et al 1960 Angaut & Brodal 1967)

PAN I was induced 6 days after lesion (Fig 30 D F) but was weaker than before lesion (Fig 30 A C) The decrease in intensity may be explained by a subtraction of the apogeotropic direction-changing positional nystagmus due to the lesion from the geotropic PAN When the positional nystagmus decreased, the nystagmus of PAN I was stronger (Fig. 30 G I) PAN I was also induced after contralateral labyrinthectomy (Fig. 30 K L) This suggests that the lesion had not directly affected portions of the vestibular nuclei which process the incoming information responsible for PAN This is in contrast to the loss of PAN after destruction of rostral DVN in 717 Caudal DVN probably maintains an indirect or secondary influence on information arising in the otolith organs

7 Lesions of the Superior Vestibular Nucleus

724

Two animals (724 & 722) had lesions which destroyed the left SVN The lesion in 724 most closely approximated an isolated destruction of SVN Its findings will be contrasted to those in 722 and 727 which had lesions in and around SVN The extent of the destruction in 724 is shown in Figs 31 and 32 The lesion was confined to SVN and to ventral portions of the brachium conjunctivum About 3/4 of SVN was destroyed Only the rostral ventral portion of SVN was not directly damaged but it was gliotic and had few remaining neurons (Fig 31 A B 32 A B) The cerebellar nuclei were normal

Electrical stimulation through the implanted electrodes with pulse trains before lesion in 724 produced upward counterclockwise rotatory eye movements ( ) On repetitive stimulation nystagmus was induced with upward counterclockwise rotatory slow phases ( ) and downward clockwise rotatory

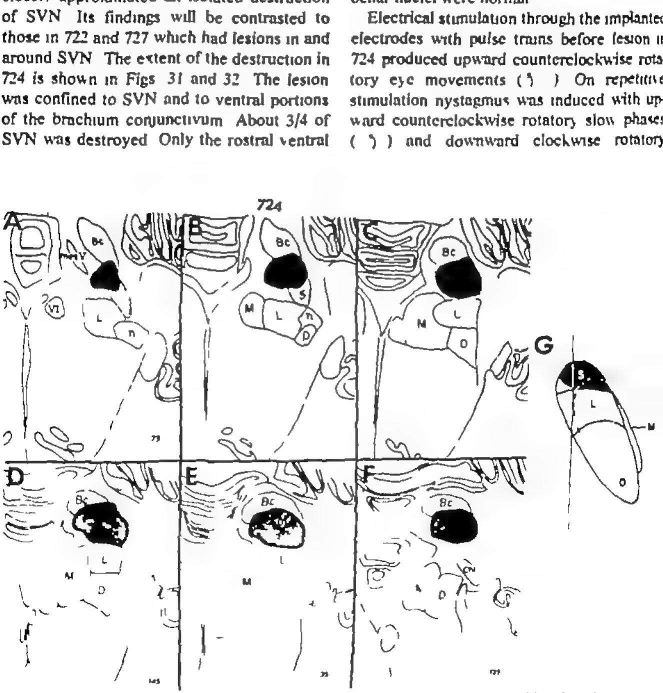

Fig 31 A F Diagram of lesion (black) and areas of demyelination and gliosis (stippled) in 724 G Sagittal view of vestibular nuclei from lateral aspect showing extent of destruction The vertical line through C shows the plane of section for A F and Figure 3

quick phases ( ) *After lesion there was a* falling tendency to the opposite side in 724 (Fig 33) The monkey could sit upright but tended to support itself on all fours There was a slight head tilt to the contralateral (right) side

Spontaneous and positional nystagmus There was upward rotatory counterclockwise spontaneous nystagmus after the lesion (Fig 34 A) This nystagmus was just opposite in direction to that induced by repetitive electrical stimulation before lesion The spontaneous nystagmus lasted for 7 days in light and 10 days in darkness

Changes in head position induced striking positional nystagmus in 724 Two days after lesion when the contralateral (right) side was down the spontaneous upward counterclockwise rotatory nystagmus became weaker (Fig. 34 C) If the animal was tilted 45 toward the side of the lesion the nystagmus reversed and was downward clockwise rotatory in direction (Fig 34 E) With the ipsilateral (left) side down strong horizontal nystagmus was induced to the left without a significant rotatory component (Fig 34 D) Positional nystagmus with the left side down was horizontal for 7 days and then was mainly downward

OKN and OKAN OKN was induced to both sides after lesion in 724 There was preponderance of OKN to the ipsilateral side for the first two weeks (Fig 35 C D) The OKN was almost symmetrical 15 days after lesion (Fig 35 E F) OKAN was present to both sides after the SVN lesion although the duration of contralateral OKAN was shorter than

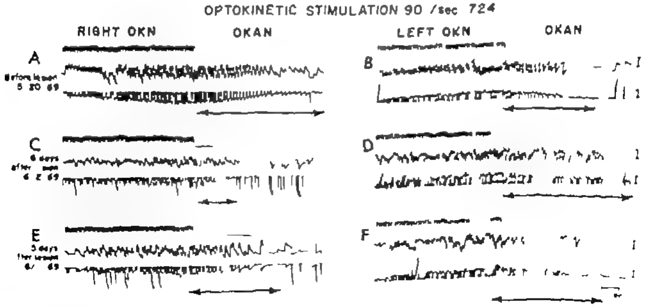

Fig 35 OKN and OKAN before (A B) and after (C–F) left SVN *lesion in 7?4 The top trace in each* pair is the photocell showing passage of drum stripes The vertical bars show ?0° of deviation for the horizontal EOG (middle trace) and 40°/sec for the slow phase velocity (bottom trace)

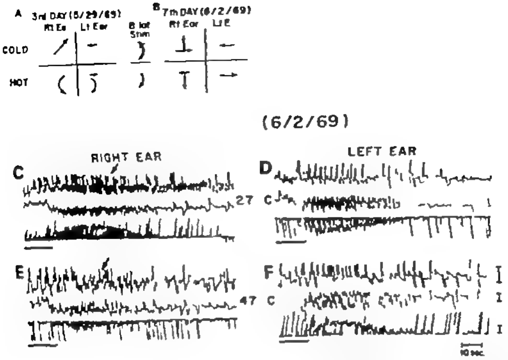

Fig 36. Nystagmus induced by caloric stimulation in 724 3 and 7 days after left SVN lesion. The arrows in A, B show the direction of the nystagmus induced by caloric stimulation. B is diagrammatic representation of C–F. The top trace in C–F is the vertical EOG, the second trace the horizontal EOG and the third trace the slow phase velocity of the horizontal component of the nystagmus. The period of stimulation is shown by the underlying black bars. The vertical bars show 20° of deviation for the vertical and horizontal EOGs and 40°/sec for the horizontal slow phase velocity. The arrows at C and E point to the pronounced vertical component of the induced nystagmus.

that of ipsilateral OKAN on the 7th (Fig 35 C D) and 15 th day (Fig 35 E F) OKAN was more strongly affected after labyrinthectomy (707 & 779) or after lesions of the dorsal medullary reticular formation (734 see below)

Caloric nystagmus Perverted nystagmus was induced by caloric stimulation in 724 We define perverted caloric nystagmus as nystagmus induced by unilateral stimulation which is predominantly vertical instead of being horizontal or horizontal rotatory Results of testing 3 days after lesion are summarized in Fig 36 A. When the contralateral (right) ear was stimulated with cold water the nystagmus was oblique upwards and to the left. When the right ear was stimulated with hot water there was downward nystagmus with a counter clockwise rotatory component. When the ipsilateral (left) ear was stimulated with cold water the induced nystagmus was predominantly horizontal to the right However stimulation of the left ear with hot water also induced ipsilateral downward clockwise rotatory nystagmus

When both ears were simultaneously stimulated with cold water strong upward nystagmus was induced with some counterclockwise rotation (Fig. 36 A Bilat. Stim). Bilateral simultaneous stimulation with hot water produced weaker downward nystagmus which was clockwise

Perverted nystagmus was still induced at the end of the first week by stimulation of the

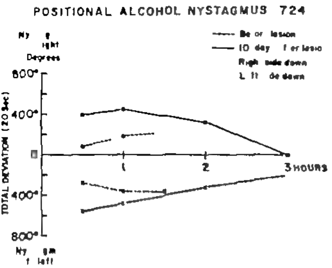

Fig 37 Graph of intensity of positional alcohol nystagmus before ( ) and after (—) lesion of left SVN in 724

contralateral ear with hot and cold water (Fig 36 B) This nystagmus is shown in Fig. 36 C–F The strong upward and downward components of the nystagmus induced by stimulation of the contralateral ear are indicated by the downward arrows over the vertical EOGs in Fig. 36 C and E (top traces) Only horizontal nystagmus was induced by stimulation of the ipsilateral ear (Fig 36 D F) There was some preponderance of the horizontal component of the nystagmus to the ipsilateral (left) side on both the 3rd and 7th day after lesion

Two weeks after lesion contralateral cold stimulation produced oblique upward nystagmus but the nystagmus caused by contralat

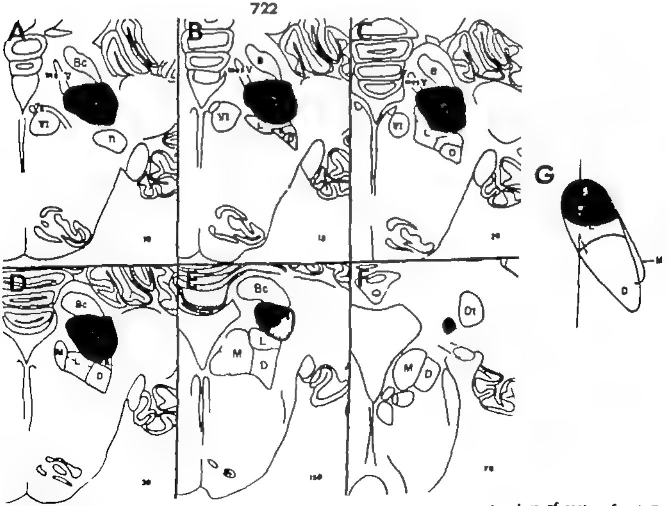

Fig 38 Diagrams of lesion in 722 A F are in the vertical stereotaxic plane and G is a diagram of the vestibular nuclei from the lateral aspect. The vertical line in G demonstrates the plane of section for A F and Figure 39

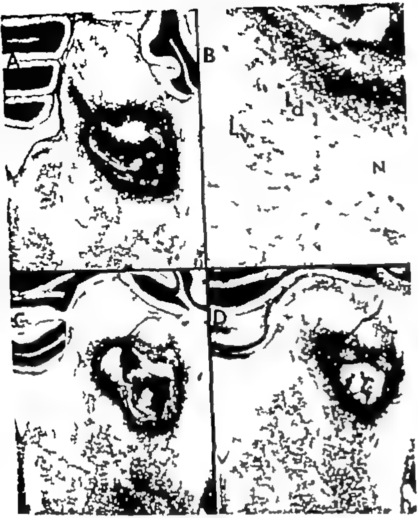

Fig. 39. Photomicrographs stained with cresyl violet of the lesion in 722. A and B correspond to Fig. 38 C, C to Fig. 38 D, and D to Fig. 38 E. *Lv*: Ventral portion of LVN (small cell area). *Ld*: Dorsal portion of LVN (giant cell area). V: Vestibular nerve.

eral hot stimulation was now mainly horizontal. With the animal upside down, downward rotatory nystagmus was induced by stimulation of the contralateral ear with cold water. This was similar to that previously induced by stimulation with hot water with the animal upright (Fig. 36 A, B, Rt. Ear Hot).

PAN. Strong direction-changing positional nystagmus was induced during PAN I 10 days after lesion (Fig. 37, solid lines). This nystagmus was more intense than before operation (dotted lines). Strong downward nystagmus was present during PAN I with the animal upright, and upward nystagmus was present when the animal was upside down.

16 days after lesion, the monkey developed continuous seizures caused by metal screws in the skull cap and was sacrificed. Contralateral labyrinthectomy was not performed.

722

The lesion was more extensive in 722 than in 714. It entirely destroyed SVN (Fig. 38 A–D, G). It also damaged ventral parts of the brachium conjunctivum (Fig. 38 C–E, 39 A, C), dorsal portions of LVN (Fig. 38 B–D, 39 A, B) and slightly impinged on the dorsal part of the vestibular nerve (Fig. 38 D). Figure 39 B is a higher magnification of the partial destruction of dorsal LVN (Ld). Brachium

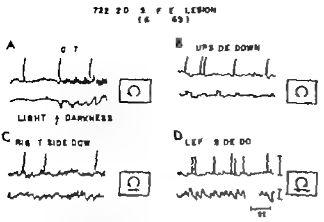

Fig 40 Spontaneous (A) and positional nystagmus (B–D) after lesion in 722 The vertical bars represent 20° for the vertical EOG (*upper trace*) and horizontal EOG (*lower trace*)

conjunctivum destruction was less in 722 than in 724 The cerebellar nuclei were normal

Aside from a slight ipsilateral head tilt and falling tendency there was little change in posture in 722 (Fig 33) This was in contrast to the more striking postural effects of the SVN lesion in 724 Stimulation through the implanted electrodes with pulse trains prior to the lesion induced ipsilateral oblique (left) eye movements (↗) With repetitive stimulation ipsilateral horizontal clockwise rotatory nystagmus was induced (↷)

Spontaneous and Positional Nystagmus After lesion the spontaneous nystagmus was counterclockwise rotatory (Fig 40 A) with a strong upward component (top trace Fig 40 A) The upward component was similar to that found in 724 (compare top traces in Figs 34 A and 40 A) Spontaneous nystagmus was present in light for about 8 days and in darkness for about 1 month

Positional nystagmus was striking in two ways in 722 (1) It was almost entirely in the coronal plane (2) The rotatory component of the nystagmus reversed direction when the animal s head position was reversed When the ipsilateral (left) side was down there was clockwise nystagmus (Fig 40 D) When the contralateral (right) side was down the nystagmus was rotatory and counterclockwise (Fig 40 C) This direction-changing rotatory positional nystagmus persisted until the animal s death 31 days after lesion A similar reversal of rotatory nystagmus due to change in head position was also present in 724 (Fig 34 A E)

OKN and OKAN There was initially a slight preponderance of OKN to the ipsilateral (left) side OKAN was present but it was initially somewhat shorter to the contralateral than to the ipsilateral side

Caloric Nystagmus On the 3rd day there was a slight directional preponderance of caloric nystagmus to the ipsilateral side The nystagmus induced by stimulation of the opposite ear with cold water or of the ear on the lesion side with hot water was accompanied

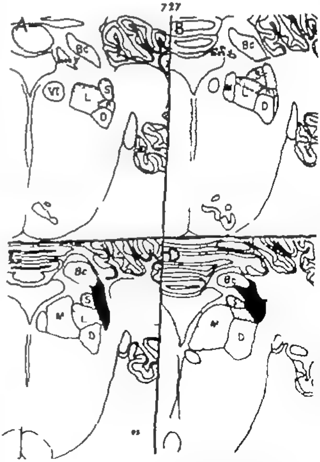

Fig 41 Diagrams of the destruction (black) and demyelination and gliosis (stippled) in 727 secs 1 Mes encephalic trigeminal nucleus VI Abducens nucleus

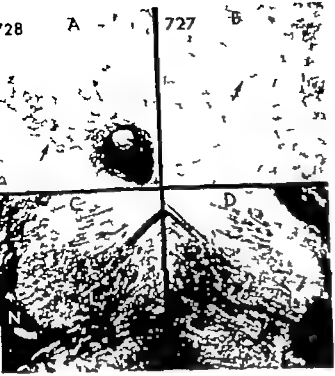

Fig 42 A. Gliosis in ventral LVN after nerve root lesion in 728 See also Figures 11 & 3 which show extent of lesion in this animal. B gliosis and, D demyelination in dorsal LVN after destruction of the brachium conjunctivum and restiform body in 727 The normal LVN and vestibular nerve on the intact side are shown in C. A, B cresyl violet and C, D Weil stains.

by an upward component The animal had a strong upward component to the spontaneous nystagmus at that time On the 8th and 16th days the nystagmus induced by hot and cold stimulation was mainly horizontal and was symmetrical

722 developed seizures presumably due to metal screws in the skull cap after 1 month and did not have a contralateral labyrinthectomy

727

This animal had a lesion in ventro-lateral parts of the brachium conjunctivum and the medial part of the restiform body (Figs. 41 C D) There was gliosis and a loss of fibers in SVN and in dorsal LVN (Fig 41) showing that much of the afferent cerebellar input to these nuclei had been interrupted There was little direct damage to SVN and ventral LVN was intact. The gliotic demyelinated dorsal LVN in 727 (Fig 4 B D arrows) can be contrasted to the normal LVN on the opposite side (Fig. 4 C) Differences in ventral LVN due to nerve root lesion in 728 and in dorsal LVN due to a brachium conjunctivum and restiform body lesion in 727 are shown in Fig 42 A B

Stimulation through the electrodes with pulse trains or repetitive stimulation prior to the lesion in 727 caused strong ipsilateral horizontal eye deviations (→) but not nystagmus After lesion there was a falling tendency to the ipsilateral side (Fig. 33)

Spontaneous and positional nystagmus Spontaneous nystagmus was not striking in 727 There was some ipsilateral counter clockwise rotatory nystagmus just after lesion (◡) and contralateral nystagmus 8 days after lesion.

Head position had some effect on the spontaneous nystagmus in this animal. As in 722 the rotatory nystagmus was intensified when the contralateral side was down. However there was no reversal of the rotatory nystagmus when the ipsilateral side was down as in 722 or in 724

OKN and OKAN 8 days after lesion

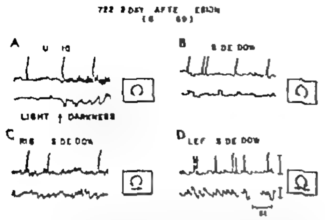

Fig 40 Spontaneous (A) and positional nystagmus (B–D) after lesion in 722. The vertical bars represent 70° for the vertical EOG (*upper trace*) and horizontal EOG (*lower trace*).

conjunctivum destruction was less in 722 than in 724 The cerebellar nuclei were normal

Aside from a slight ipsilateral head tilt and falling tendency there was little change in posture in 722 (Fig 33) This was in contrast to the more striking postural effects of the SVN lesion in 724 Stimulation through the implanted electrodes with pulse trains prior to the lesion induced ipsilateral oblique (left) eye movements ( ) With repetitive stimulation ipsilateral horizontal clockwise rotatory nystagmus was induced ( )

Spontaneous and Positional Nystagmus After lesion the spontaneous nystagmus was counterclockwise rotatory (Fig 40 A) with a strong upward component (top trace Fig 40 A) The upward component was similar to that found in 724 (compare top traces in Figs 34 A and 40 A) Spontaneous nystagmus was present in light for about 8 days and in darkness for about 1 month

Positional nystagmus was striking in two ways in 722 (1) It was almost entirely in the coronal plane (2) The rotatory component of the nystagmus reversed direction when the animal's head position was reversed When the ipsilateral (left) side was down there was clockwise nystagmus (Fig 40 D) When the contralateral (right) side was dowr the nystagmus was rotatory and countercloc wise (Fig 40 C) This direction-changin rotatory positional nystagmus persisted unt the animal's death 31 days after lesion similar reversal of rotatory nystagmus due t change in head position was also present i 724 (Fig 34 A E)

OKN and OKAN There was initially slight preponderance of OKN to the ips lateral (left) side OKAN was present but i was initially somewhat shorter to the contra lateral than to the ipsilateral side

Caloric Nystagmus On the 3rd day ther was a slight directional preponderance o caloric nystagmus to the ipsilateral side Th nystagmus induced by stimulation of th opposite ear with cold water or of the ear o the lesion side with hot water was accompanie

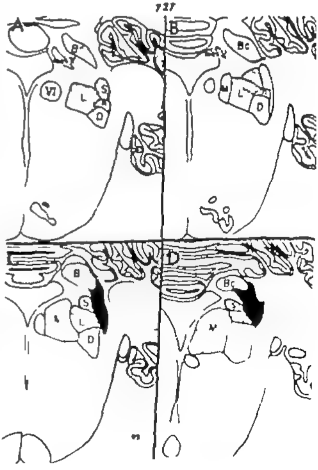

Fig 41 Diagrams of the destruction (black) and demyelination and gliosis (stippled) in 722 M Mesencephalic trigeminal nucleus VI Abducens nucleus

in view of the inhibitory nature of the cerebello-vestibular pathways from the flocculus (Ito et al 1970 Baker et al 1972 Fukuda et al. 1977) One possibility is that interruption of these pathways may have resulted in some dysinhibition of otolith-ocular reflexes. This is consistent with the finding that PAN was enhanced after the lesion in 724 and that active downward nystagmus appeared in the upright position during PAN I There are no (Gacek, 1969) or few (Stein & Carpenter 1967) direct afferent projections from the otolith organs to SVN so that presumably the positional nystagmus is related to activity mediated through the cerebellum

The horizontal component of caloric nystagmus was preserved in 722 and 724 although SVN was partially or completely destroyed The main effect of the SVN lesions on horizontal nystagmus was to cause some ipsilateral directional preponderance If a primary area for production of horizontal caloric nystagmus were destroyed one would expect contralateral directional preponderance and spontaneous nystagmus as after labyrinthectomy (707 729). It can be concluded that SVN is not an essential nucleus for production of horizontal nystagmus induced by the lateral semicircular canal

The main effect of the SVN lesions on caloric nystagmus was an enhancement of vertical components particularly when induced by stimulation of the ear on the *contralateral* (right) side According to arguments given in the Methods Section a unilateral caloric stimulus simultaneously excites both the lateral and anterior semicircular canals although horizontal nystagmus from the lateral canal predominates in the observed response The accentuation of vertical caloric responses on right-sided stimulation seemed most likely to be due to an enhancement of nystagmus induced by the right anterior canal.Nystagmus with similar vertical and rotatory components would be induced by excitation or inhibition of the right anterior canal but could not be produced by the right posterior canal (Fig. 3 D E) Speculative explanations for the enhancement or dysinhibition of the anterior canal responses will be considered in the General Discussion

there was some preponderance of OKN to the right which agreed with the direction of the spontaneous nystagmus OKAN was reduced to the ipsilateral side

Caloric nystagmus Three days after lesion caloric nystagmus was stronger when quick phases were to the ipsilateral side Later the spontaneous nystagmus reversed and caloric nystagmus was stronger when it was to the opposite side 3 days after lesion an upward component was present when the ipsilateral ear was stimulated with hot or the contralateral ear with cold water When both ears were simultaneously stimulated with cold water on the 8th day strong upward nystag mus was induced No downward nystagmus was induced by bilateral hot stimulation at that time

Comment

Two major projection systems end in SVN They come from the ipsilateral semicircular canals (Stein & Carpenter 1967 Gacek 1969) and from the cerebellum (Walberg et al 1962 Angaut & Brodal 1967) 724 had a fall ing tendency to the contralateral side spon taneous nystagmus with a definite ipsilateral component and ipsilateral directional prepon derance of OKN and caloric nystagmus None of these findings occur after unilateral laby rinthectomy Therefore the findings in 724 could not be attributed solely to a reduction of afferent inflow from the ipsilateral semi circular canals

Similarly body postural changes were differ ent in 724 after SVN destruction than in 727 after a lesion of cerebello-vestibular path ways 727 had a strong falling tendency to the ipsilateral side while in 724 the falling tend ency was to the contralateral side Thus the postural changes in 724 were not due to damage of cerebello-vestibular pathways Rather the postural changes appeared to be due to intrinsic damage to SVN itself Another monkey (453) had more extensive destruction of the brachium conjunctivum but also did not have similar postural changes or spontaneous nystagmus as 724 McMasters et al (1966) also noted that monkeys with SVN lesions tended to develop head tilt toward the opposite shoulder

Postural changes in 724 and 722 (Fig 33) are the reverse of what might be expected from the size of the lesions The lesion in 722 was the largest of any in the series yet the postural changes were less than in 724 A speculative explanation for this is that there was a summation of postural changes produced by lesions of several different struc tures That is contralateral head and body tilt due to SVN destruction (Fig 33 724) may have added the ipsilateral head and body tilt due to LVN or vestibular nerve lesions (Fig 13 A) or restiform body lesions (Fig 33 727) to produce the relatively minor overt effect on body posture in 722 Postural effects were tested only by observing the ani mals sitting and walking just after lesion and more subtle changes would be missed

The direction of the spontaneous nystagmus after lesion in 724 was just the reverse of the nystagmus induced by stimulation It would appear that the left SVN lesion had caused a change in eye movements in spatial planes represented by the left anterior or right posterior canal (Fig 3 D E also Suzuki et al 1964 Suzuki & Cohen 1964 Cohen et al 1966) Nystagmus with these rotatory and vertical components would not be induced either by excitation or destruction of the left posterior or right anterior canals (Fig 3 D E)

There was positional nystagmus in each of the animals with lesions of SVN (722 724) or of afferent pathways to SVN (727) It was counterclockwise when the right side was down in all 3 monkeys (Fig 34 C 40 C) and clockwise when the left side was down in 722 (Fig 40 D) or when the head was 45° to the left in 724 (Fig 34 E) There was no clockwise nystagmus when the ipsi lateral side was down in 727 The prominent positional nystagmus with the contralateral side down in all three animals is of interest

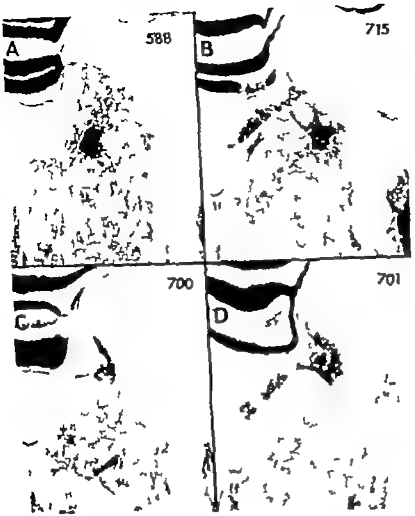

Fig 44 Photomicrographs through the center of the lesions in 588 715 700 and 701 Cresyl violet stain.

However in 701 the lesion extended laterally and there was some involvement of SVN and LVN (Fig 43 D stippled area) In 73? the lesion was much larger than in the other MVN animals Central parts of MVN were destroyed at the junction with DVN (Fig 45 A B) but rostral MVN was intact (Fig. 45 A Inset 45 B)

Postural effects of the MVN lesions were minimal There was no head tilt or falling tendency in monkeys with lesions of rostral MVN (588 700 701) or central MVN (73) Fig. 46 A) In 715 there was a slight head tilt and falling tendency to the contralateral side (Fig. 46 B).

Spontaneous and positional nystagmus Spontaneous nystagmus was not prominent in these animals It was present for not more than ? days in light and 5 days in darkness in all but 701 In that animal it was present until the 13th day The spontaneous nystagmus was contralateral in 588 and 732 and ipsilateral in 700 701 and 715

Positional nystagmus was also not prominent in 4 of the 5 animals after MVN lesions In 701 geotropic direction-changing positional nystagmus was induced with some upward vertical component in the EOG

OKN and OKAN Changes in OKN were relatively minor after MVN lesions and

8 Lesions of the Medial Vestibular Nucleus

Five animals had lesions of the left MVN 588 700 701 715 and 732. In 588 the destruction was confined to rostral MVN It was about 1 mm wide and extended about 1 5 mm in rostro-caudal direction (Fig 43 A) The lesion was surrounded by a zone of gliosis which extended through rostral MVN (Fig 44 A) Neither the central nor caudal portions of MVN nor the other vestibular nuclei were affected in 588 In 715 the lesion destroyed the lateral dorsal part of rostral MVN and part of the adjacent LVN (Fig. 43 B 44 B) The lesion was more lateral and dorsal than in 588 In 700 and 701 the lesions were about 1 mm in diameter and were almost identical destroying the rostrodorsal portions of left MVN at the junction with the fourth ventricle (Fig 43 C D 44 C D)

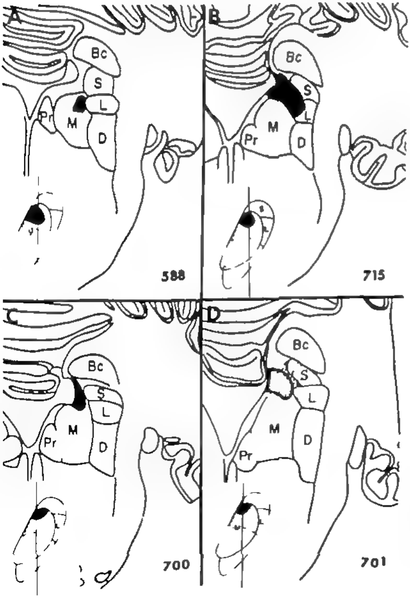

Fig 43 Diagrams of lesion (black) and areas of demyelination and gliosis (stippled) in 588 715 700 and 701 The insets show the extent of the lesions in sagittal drawings of the vestibular nuclei seen from the medial aspect The vertical lines show the plane of section in Figures 43 & 44

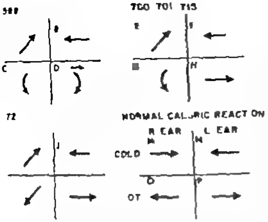

Fig. 47 Diagrammatic representation of nystagmus induced by hot and cold caloric stimulation in Monkeys 588 (A–D), 700, 701, and 715 (E–H), and 774 (I–L). The direction of quick phases of nystagmus in the normal caloric reaction is shown in M–P. Note that stimulation of the contralateral (right) ear with cold water induced upward oblique nystagmus and hot water downward counterclockwise rotatory nystagmus after either the left MVN or SVN lesions

to the contralateral side in 700, 701, and 715 and to the ipsilateral side in 588.

Caloric nystagmus. Caloric nystagmus was affected in a characteristic way by lesions of the rostral portion of MVN. The nystagmus is represented diagrammatically in Fig. 47 and examples of EOGs are shown in Fig. 48 for 588 and 700. Findings in 701 and 715 were similar to those in 700. Vertical components are shown in the top traces of Fig. 48 and horizontal components in the 2nd and 3rd traces. These record the vertical EOG, the horizontal EOG and the horizontal slow phase velocity, respectively.

When the ear on the side *contralateral* to the lesion (right) was stimulated, the induced nystagmus was predominantly vertical. With hot water, downward counterclockwise nystagmus was induced (Fig. 47 C, G). There was little or no horizontal component in the nystagmus (Fig. 48 C, G middle and bottom traces). When the right ear was stimulated with cold water, the induced nystagmus was oblique upward (Fig. 47 A, E). The horizontal component of this nystagmus was preserved (Fig. 48 A, E middle and bottom traces). Changes in vertical components of nystagmus induced from the contralateral ear were long-lasting in 588 (more than 3 months) and were of shorter duration in 700, 701, and 715 (about 1 month). Later, contralateral cold stimulation induced predominantly horizontal nystagmus in these animals.

When the ear ipsilateral to the lesion side (left) was stimulated with cold water, the induced nystagmus was horizontal in all 4 animals (Fig. 47 B, F, 48 B, F). Stimulation of the left ear with hot water provoked downward clockwise nystagmus in 588 for more than 3 months (Fig. 47 D, 48 D). In 700, 701, and 715 only horizontal nystagmus was induced by ipsilateral hot stimulation (Fig. 47 H, 48 H).

588 was tested when upside down. The response to stimulation with hot and cold water was the reverse of the patterns shown in Fig. 47 A–D. Double simultaneous hot and cold stimulation in 588 in the upright position produced active downward and upward vertical nystagmus in the midsagittal plane, respectively.

PAN. PAN was not affected in any of the animals with MVN lesions. Geotropic direction-changing PAN in 715, which was somewhat more active after than before lesion, is shown in Fig. 49 B.

Labyrinthectomy. 715 had a right labyrinthectomy. After operation there was a strong head tilt and falling tendency to the right (Fig. 46 C). Spontaneous nystagmus was present to the left. It persisted in darkness until sacrifice 4? days later. This nystagmus was increased when the side of the labyrinthectomy was down and decreased when the contralateral side was down. There was directional preponderance of OKN in the same direction as the spontaneous nystagmus. OKAN was induced after right labyrinthectomy but was of short duration, ipsilateral less than contralateral.

Nystagmus to the right and left was induced

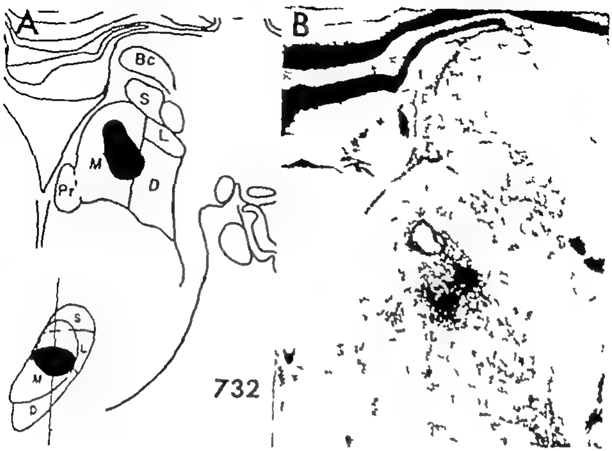

Fig 45 A Diagrams and B photomicrograph through the center of the lesion in 73? The inset in A is a sagital view of the vestibular nuclei from the medial aspect showing the extent of destruction and the plane of section.

agreed with the direction of the spontaneous nystagmus In 700 701 and 715 there was ipsilateral preponderance of OKN for about 1 week In 588 the OKN preponderance was to the contralateral side OKN was not tested in 732 Changes in OKAN were also relatively minor and mirrored the spontaneous nystag mus The duration of OKAN was decreased

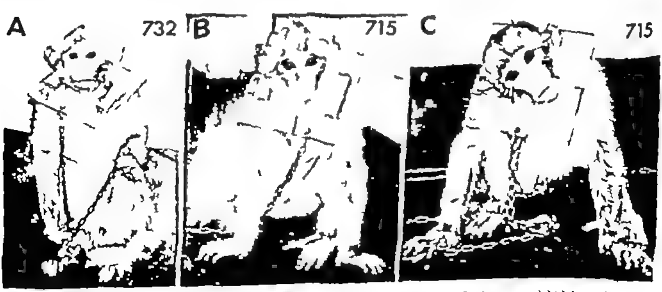

Fig 46 Head position and body posture in 732 (A) after a central MVN lesion and (B) in 715 after a rostral MVN lesion Effect of subsequent right labyrinthectomy in 715 are show n C

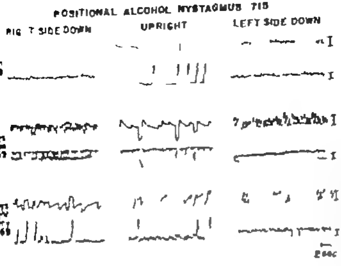

Fig. 49. EOGs showing spontaneous and positional alcohol nystagmus before (A), after (B) left MVN lesion in 715. Effects of right labyrinthectomy are shown in C. The vertical bars show 30° of deviation for the horizontal EOG (*upper trace*) and 60°/sec for the slow phase velocity (*bottom trace*).

the descending projections from rostral and central MVN was not elucidated by this study.

Spontaneous nystagmus was ipsilateral in 3 of 5 monkeys (700, 701, and 715) and transiently contralateral in the other two animals (588, 732). Similarly, nystagmus was ipsilateral after SVN destruction.

Positional nystagmus was not present in 588, 700, 715, and 732. Morever, PAN was not abolished by the MVN lesion after contralateral labyrinthectomy in 715. Although there was some positional nystagmus in 701, it seems likely that it was due to involvement of adjacent parts of SVN. Rostral MVN does not appear to be a critical area for processing information which originates in the otolith organs.

The horizontal component of caloric nystagmus induced by stimulation of either ear with cold water was preserved in each of the animals after rostral and central MVN lesions. These findings indicate that portions of rostral and central MVN which were destroyed were not critical for production of horizontal nystagmus induced by the lateral semicircular canals. The weak spontaneous nystagmus after MVN lesions is in accord with this conclusion. Spontaneous nystagmus was much stronger after unilateral labyrinthectomy (707, 729) or after root entry zone destruction (728).

Perverted nystagmus with enhanced vertical components induced by stimulation of the contralateral ear was similar in animals with MVN (Fig. 47 A, C, E, G) and SVN lesions (Fig. 47 I, K). The perverted nystagmus persisted for a longer time after the MVN lesion in 588 and in addition persistent perverted nys-

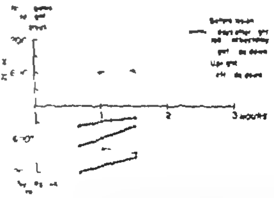

Fig. 50. Graph of intensity of nystagmus during PAN before ( ) and after left MVN lesion and contralateral (*right*) labyrinthectomy (——) in 715. The strong spontaneous nystagmus (●—●) after the left MVN lesion and right labyrinthectomy was enhanced in the left-side down position (—) and reduced in the right-side down position (○—○).

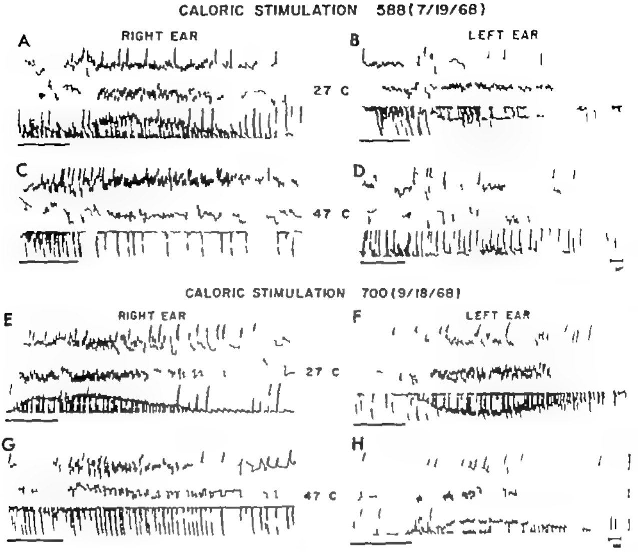

Fig 48 Caloric nystagmus in 588 (A D) and 700 (E–H) after left MVN lesions The nystagmus is represented diagrammatically in A–H of Figure 47 The top trace is the vertical EOG The second trace is the horizontal EOG and the lower trace records horizontal slow phase velocity Note the strong upward and downward nystagmus in the vertical EOG (top trace of A C E & G) when the contralateral (*right*) ear was stimulated with cold or hot water The horizontal component of the response to stimulation of the right ear with hot water (2nd and 3rd traces of C & G) was also markedly diminished The vertical bars show 5° of deviation for the vertical and horizontal EOG and 50°/sec for horizontal slow phase velocity (bottom trace)

by hot and cold stimulation of the left ear respectively after contralateral labyrinthectomy

Alcohol administration 8 days after labyrinthectomy caused a diminution of slow phase velocity of the spontaneous nystagmus when the labyrinthectomy side (right) was down and an increase in slow phase velocity when the contralateral side was down (Fig 49 C 50 solid lines)

Comment

Postural changes were not striking after lesions in any of the animals after MVN lesions 715 had a slight contralateral head tilt but it was minimal Neurons in MVN send axons to the spinal cord via the MLF The spinal projection of MVN is much smaller than its ascending projection (Wilson et al 1968 a) or than the vestibulospinal projection from LVN (Nyberg Hansen 1964) The function of

Rostral MVN does not appear to be a critical area for processing information which originates in the otolith organs.

The horizontal component of caloric nystagmus induced by stimulation of either ear with cold water was preserved in each of the animals after rostral and central MVN lesions. These findings indicate that portions of rostral and central MVN which were destroyed were not critical for production of horizontal nystagmus induced by the lateral semicircular canals. The weak spontaneous nystagmus after MVN lesions is in accord with this conclusion. Spontaneous nystagmus was much stronger after unilateral labyrinthectomy (707, 729) or after root entry zone destruction (728).

Perverted nystagmus with enhanced vertical components induced by stimulation of the contralateral ear was similar in animals with MVN (Fig. 47 A, C, E, G) and SVN lesions (Fig. 47 I, K). The perverted nystagmus persisted for a longer time after the MVN lesion in 588 and in addition persistent perverted nys-

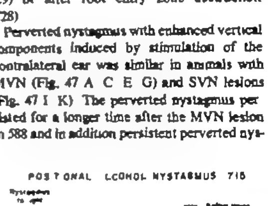

Fig. 50. Graph of intensity of nystagmus during PAN before ( ) and after left MVN lesion and contralateral (right) labyrinthectomy (——) in 715. The strong spontaneous nystagmus (●—●) after the left MVN lesion and right labyrinthectomy was enhanced in the left-side down position (—) and reduced in the right-side down position (○—○).

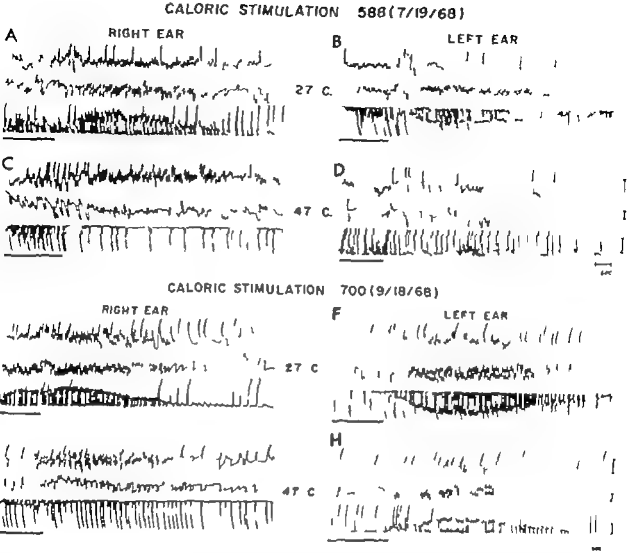

Fig 48 Caloric nystagmus in 588 (A–D) and 700 (E–H) after left MVN lesions The nystagmus is represented diagrammatically in A H of Figure 47 The top trace is the vertical EOG The second trace is the horizontal EOG and the lower trace records horizontal slow phase velocity Note the strong upward and downward nystagmus in the vertical EOG (top trace of A C E & G) when the contralateral (*right*) ear was stimulated with cold or hot water The horizontal component of the response to stimulation of the right ear with hot water (2nd and 3rd traces of C & G) was also markedly diminished The vertical bars show 5° of deviation for the vertical and horizontal EOG and 50°/sec for horizontal slow phase velocity (bottom trace)

by hot and cold stimulation of the left ear respectively after contralateral labyrinthectomy

Alcohol administration 8 days after labyrinthectomy caused a diminution of slow phase velocity of the spontaneous nystagmus when the labyrinthectomy side (right) was down and an increase in slow phase velocity when the contralateral side was down (Fig 49 C 50 solid lines)

Comment

Postural changes were not striking after lesions in any of the animals after MVN lesions 715 had a slight contralateral head tilt but it was minimal Neurons in MVN send axons to the spinal cord via the MLF The spinal projection of MVN is much smaller than its ascending projection (Wilson et al 1968 a) or than the vestibulospinal projection from LVN (Nyberg Hansen 1964) The function of

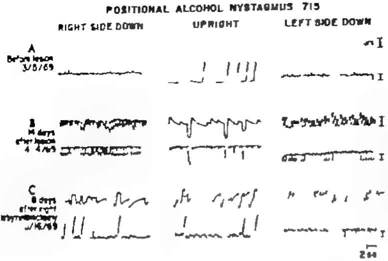

Fig 49 EOGs showing spontaneous and positional alcohol nystagmus before (A), after (B) left MVN lesion in 715. Effects of right labyrinthectomy are shown in C. The vertical bars show 30° of deviation for the horizontal EOG (*upper trace*) and 60°/sec for the slow phase velocity (*bottom trace*)

the descending projections from rostral and central MVN was not elucidated by this study

Spontaneous nystagmus was ipsilateral in 3 of 5 monkeys (700 701 and 715) and transiently contralateral in the other two animals (588 732). Similarly nystagmus was ipsilateral after SVN destruction

Positional nystagmus was not present in 588 700 715 and 732. Morever PAN was not abolished by the MVN lesion after contralateral labyrinthectomy in 715. Although there was some positional nystagmus in 701 it seems likely that it was due to involvement of adjacent parts of SVN. Rostral MVN does not appear to be a critical area for processing information which originates in the otolith organs

The horizontal component of caloric nystagmus induced by stimulation of either ear with cold water was preserved in each of the animals after rostral and central MVN lesions. These findings indicate that portions of rostral and central MVN which were destroyed were not critical for production of horizontal nystagmus induced by the lateral semicircular canals. The weak spontaneous nystagmus after MVN lesions is in accord with this conclusion. Spontaneous nystagmus was much stronger after unilateral labyrinthectomy (707 729) or after root entry zone destruction (728)

Perverted nystagmus with enhanced vertical components induced by stimulation of the contralateral ear was similar in animals with MVN (Fig. 47 A C E G) and SVN lesions (Fig. 47 I K). The perverted nystagmus persisted for a longer time after the MVN lesion in 588 and in addition persistent perverted nys

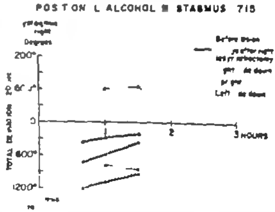

Fig 50 Graph of intensity of nystagmus during PAN before ( ) and after left MVN lesion and contralateral (*right*) labyrinthectomy (——) in 715. The strong spontaneous nystagmus (●—●) after the left MVN lesion and right labyrinthectomy was enhanced in the left-side down position (—) and reduced in the right-side down position (○—○)

tagmus was induced by ipsilateral hot stimulation (Fig 47 D) This suggests that the perversion after MVN lesions was not only due to loss of activity which originated in SVN but to an intrinsic effect of MVN on the perverted responses as well After both MVN and SVN lesions the vertical responses were more striking and were induced for longer periods of time with hot than with cold stimuli with the animals upright The reverse was true with the animals upside down This indicates that perversion was greater when there was an increase rather than a decrease in acitivity in the primary afferent vestibular nerve fibers

9 Lesions Medial to the MVN

Two monkeys 586 and 734 had lesions just medial to left MVN These lesions involved the dorsal medullary reticular formation and the prepositus hypoglossi between MVN and the MLF (Figs 51 & 52 A & B) In 586 the lesion began just behind the abducens nucleus and lay medial to MVN in its central portion (Fig. 51 A) In 734 the lesion was larger It began at the caudal lateral end of the abducens nucleus, and was located in the dorsal medullary reticular formation and the medial portion of central MVN (Fig. 52 B) There was some gliosis and cell loss in the most medial portions of MVN in both animals.

The findings in these animals were similar The animals had a strong head tilt and a falling tendency to the ipsilateral side (Fig 53 A) The head tilt was stronger in 734 than in 586 and persisted for one month until right labyrinthectomy

Spontaneous gaze and positional nystagmus Both monkeys initially had gaze nystagmus on either right or left lateral gaze Gaze nystagmus persisted on looking to the ipsilateral (left) side for more than 1 month There was also ipsilateral spontaneous nystagmus in darkness in both animals during the period of observation Geotropic direction-changing positional nystagmus was present in 586 for 3 months In 734 the spontaneous nystagmus to the ipsilateral side had a tendency to increase when the contralateral side was down

OKN There was strong directional preponderance of OKN to the ipsilateral (left) side in both animals after lesion The left directional preponderance persisted in 734 until right labyrinthectomy 29 days later (Fig. 54 B C) In 586 it was present for more than 2 months OKAN was lost after the medullary reticular formation lesion in both of these animals. It was absent at the time of right labyrinthectomy in 734 (Fig. 54 C) Some OKAN was present on the 38th day in 586 (Lt>Rt)

Caloric nystagmus The direction of caloric nystagmus was not changed by lesions in 586 and 734 There was directional pre

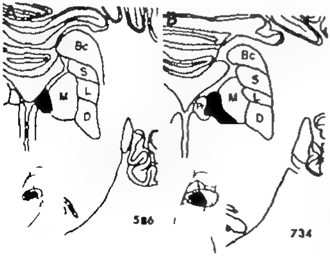

Fig 51 Diagrams of the lesions in 586 and 734 The insets show the lesions placed against the vestibular nuclei as seen from the medial aspect. The circles show the extent of lesion and the black areas, the regions where the lesion affected the adjacent parts of MVN The vertical lines show the plane of section.

Fig 52 Photomicrographs from 586 (A) and 734 (B) of the sections shown in Figure 51

ponderance to the ipsilateral (left) side (Figs 55 & 56 A) but it was not as strong as the directional preponderance of OKN (Fig 54 B) and disappeared within a month The left directional preponderance was not reflected in differences in nystagmus duration in 734 (Fig 56 B) Bilateral cold and hot stimulation induced upward and downward nystagmus respectively after the lesion in 586

PAN PAN was unaffected by the lesions in these animals

Labyrinthectomy 734 had a right labyrinthectomy 29 days after lesion Before operation there was still a slight head tilt to the ipsilateral (left) side at the time of operation Following operation the head tilt disappeared (Fig 53 B) There was no falling tendency Spontaneous nystagmus was present to the left in light and in darkness for 1 month until sacrifice Associated with the spontaneous nystagmus to the left there was also strong directional preponderance of OKN to the left There was no OKAN in either direction after labyrinthectomy (Fig. 54 D)

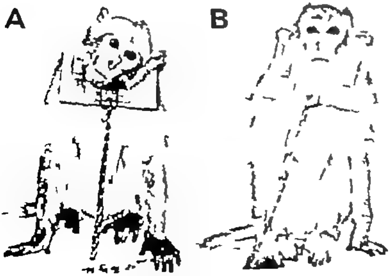

Fig 53 Head position and body posture in 734 after left dorsal medullary reticular formation lesion (A) and right labyrinthectomy (B)

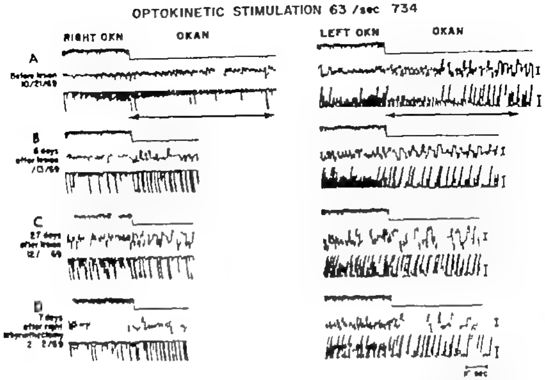

Fig 54 Optokinetic nystagmus and after-nystagmus in 734 before lesion (A), 6 and 27 days after lesion (B C) and after right labyrinthectomy (D). Note the absence of OKAN 6 and 77 days after lesion and after right labyrinthectomy The vertical bars show 22° for the horizontal EOG (second trace) and 45°/sec for the slow phase velocity (third trace).

Caloric nystagmus was induced to either side after labyrinthectomy It reflected the directional preponderance to the left That is the response to the left induced by hot water was stronger than that to the right induced by cold water

PAN was present to the right and to the left 1 and 25 days after lesion

Comment

There were a number of differences between animals with dorsal medullary reticular formation lesions (734 and 586) and animals which have been described previously (1) There was a strong ipsilateral head tilt in 586 and 734 In animals with lesions of the adjacent rostral or central MVN the head tilt was to the contralateral side or was not striking (2) The direction of head tilt after the lesion in 586 and 734 was the same as the direction of the quick phases of the spontaneous nystagmus. This is in contrast to monkeys with lesions inside the vestibular nuclei. In these animals the head tilt and falling tendency were to the same side as the slow phases of the spontaneous nystagmus.

(3) Gaze nystagmus was present for more than one month in both 586 and 734 Gaze nystagmus was not found after lesions of the vestibular nuclei (4) Changes in OKN were striking and of long duration and OKAN was abolished for considerable periods or was lost in these animals Neither OKN nor OKAN was similarly affected in any animals with vestibular nuclei lesions (5) Caloric nystagmus and PAN were not as severely

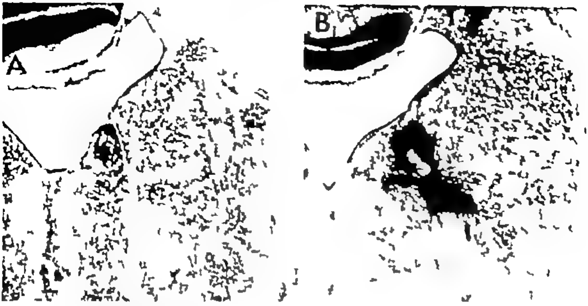

Fig 52 Photomicrographs from 586 (A) and 734 (B) of the sections shown in Figure 51

ponderance to the ipsilateral (left) side (Figs 55 & 56 A) but it was not as strong as the directional preponderance of OKN (Fig 54 B) and disappeared within a month The left directional preponderance was not reflected in differences in nystagmus duration in 734 (Fig 56 B) Bilateral cold and hot stimulation induced upward and downward nystagmus respectively after the lesion in 586

PAN PAN was unaffected by the lesions in these animals

Labyrinthectomy 734 had a right labyrinthectomy 29 days after lesion Before operation there was still a slight head tilt to the ipsilateral (left) side at the time of operation Following operation the head tilt disappeared (Fig 53 B) There was no falling tendency Spontaneous nystagmus was present to the left in light and in darkness for 1 month until sacrifice Associated with the spontaneous nystagmus to the left there was also strong directional preponderance of OKN to the left There was no OKAN in either direction after labyrinthectomy (Fig 54 D)

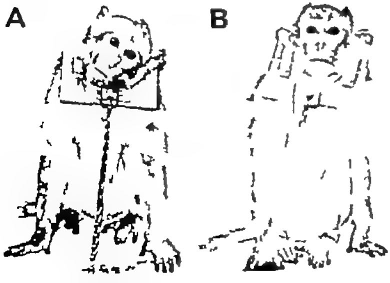

Fig 53 Head position and body posture in 734 after left dorsal medullary reticular formation lesion (A) and right labyrinthectomy (B).

present after lesions of the dorsal medullary reticular formation.

There is no clear explanation for the long lasting positional nystagmus in 586 734 with a larger lesion in the same area did not have positional nystagmus Despite the close proximity of MVN and the dorsal medullary reticular formation the differences in oculomotor and postural changes after lesions show that these regions must function quite separately

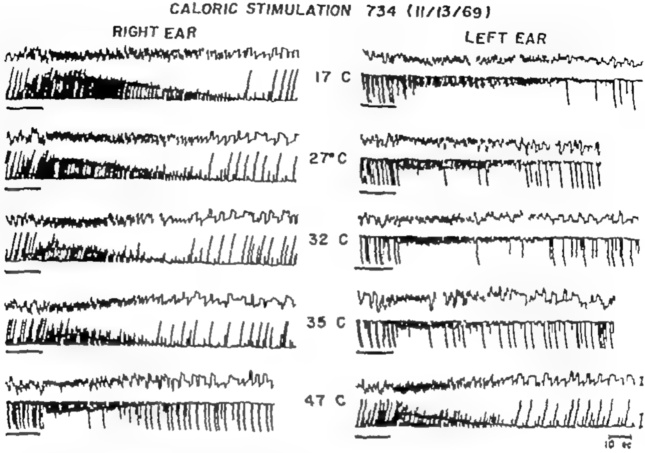

Fig 55 Nystagmus induced by stimulation of the right and left ears with different water temperatures in 734 The top trace is the horizontal EOG the second trace is slow phase velocity and the bar under the slow phase velocity trace shows the duration of stimulation. The vertical bars are 22° for the horizontal EOG and 45°/sec for the slow phase velocity

affected as OKN by the dorsal medullary reticular formation lesions Therefore it seems likely that the damage was not in primary pathways which carry information from the semicircular canals or otolith organs to the eye muscle motor nuclei Enhanced vertical components of caloric nystagmus i e perverted caloric responses were also not

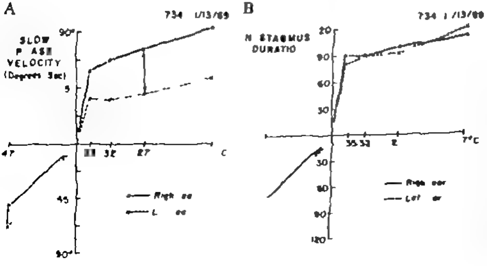

Fig 56 Graphs of slow phase velocity (A) and duration (B) of caloric nystagmus shown in Figure 55 This monkey (734) had strong directional preponderance of nystagmus to the left which was manifest in slow phase velocity (A) but was not expressed in nystagmus duration (B)

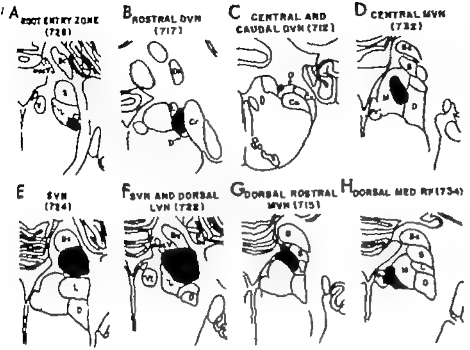

Fig 57 Diagrams of lesions in 728 (A), 717 (B), 712 (C), 732 (D), 734 (E), 722 (F), 715 (G), and 734 (H)

of afferent pathways from the cerebellum to SVN and possibly to the reticular formation It seems unlikely that dorsal LVN plays a significant role in mediating vestibulo-ocular reflexes

Horizontal caloric nystagmus was strongly affected by the nerve root lesion in 728 and the nerve root-rostral DVN lesion in 717 In both animals the lesions caused heavy degeneration of fibers in ventral LVN Rostral DVN was unaffected in 728 Since the defect in caloric nystagmus was not worse after the addition of the rostral DVN lesion in 717 we would infer that changes in caloric nystagmus in this animals were not related to the destruction of this nucleus but were due to the loss of vestibular nerve fibers which project to ventral LVN A similar loss of horizontal caloric nystagmus did not occur after lesions of other parts of the vestibular complex. This suggests that ventral LVN is an important primary projection area for afferent information from the lateral semicircular canals which induces horizontal caloric nystagmus

There has been little information to date about what role if any ventral LVN might play in mediating ocular reflexes from the semicircular canals or otolith organs Peterson (1970) found units in ventral LVN which were related to head tilt indicating some relation of ventral LVN to the otolith organs On the other hand Sans et al (1972) found that most units in ventral LVN which were monosynaptically linked to the vestibular apparatus were excited by semicircular canal nerve stimulation Desole & Pallestrini (1969) suggested that neurons in this area were only nonspecifically activated by the semicircular canals One possible source of confusion in interpreting the results in various unit studies is that the extent of ventral LVN is usually not indicated in any detail and differences in defining the limits of this nucleus could cause considerable apparent variation in results.

10 General Discussion

A PHYSIOLOGICAL IMPLICATIONS

Analysis of a complex sensory motor control system cannot be accomplished by anatomic or electrophysiological techniques alone The system must also be viewed from the stand point of performance or of changes in per formance after lesions of its component parts In previous studies of changes in vestibulo-ocular reflexes after vestibular nuclei lesions there was inadequate localization of lesions or inadequate description of the results of testing In this report we have attempted to show the extent of the lesions in several planes and to present objective evidence wherever possible to demonstrate the changes in eye movements In relation to the complexity of the vestibular nuclei and of vestibulo-ocular reflexes the number of animals with lesions was small and the testing techniques were relatively limited in scope For example the posterior semicircular canals were probably not tested (Fig 3 Chapter 2) Neither angular nor linear movement was used nor was counter rolling elicited Therefore this must be considered in the nature of a pilot study However a number of tentative conclusions and speculations can be made about oculomotor and postural function of the vestibular nuclei from the data

According to the different effects of lesions on eye movements and posture the vestibular nuclei can be subdivided into a number of regions These include (1) root entry zone and ventral LVN (2) dorsal LVN (3) rostral DVN (4) caudal DVN (5) SVN (6) rostral MVN (7) central or caudal MVN Differences in test findings have also been noted after lesions of the dorsal medullary tegmentum near the prepositus hypoglossi The effects of lesions in several of these regions will be discussed separately To aid in this discussion lesions in some of the most important animals are summarized in Fig 57 Postural changes and spontaneous nystagmus after lesion and after contralateral labyrinthectomy in these animals are shown in Fig 58 The monkeys are placed on a diagram of the vestibular nuclei over the approximate location of their lesions Photographs of 717 which had a right sided lesion were reversed to be consistent with the other animals The thin arrows and numbers over each monkey s head show the direction and duration of the spontaneous nystagmus The heavy arrows point to the posture after contralateral labyrinthectomy

The lateral vestibular nucleus None of the animals had isolated destruction of LVN but some deductions can be made about the function of this nucleus The afferent input and vestibulo-spinal projections of dorsal and ventral portions of LVN are different (Pompeiano & Brodal 1957 a Walberg et al 1958 Pompeiano 1960 Ito et al 1964 1969 Nyberg Hansen & Mascitti 1964 Wilson et al 1966 1967 *a*) Findings in 727 and 728 support this subdivision

In 728 the gliosis and fiber loss in LVN after destruction of the vestibular nerve trunk at the root entry zone was limited to the ventral part (728 Fig 57 A) This is in agreement with Walberg et al s (1958) conclusions that primary vestibular afferents enter ventral not dorsal LVN After a lesion of the restiform body in 727 gliosis and demyelination due to interruption of cerebello-vestibular pathways was prominent in the dorsal part of LVN and in SVN Ventral LVN was unaffected Changes in oculomotor function in 727 could be attributed to interruption

Similarly, although projections from ventral LVN to the spinal cord are well known, there is some controversy as to whether or not LVN projects to eye muscle motor nuclei. Electric stimulation in the region of ventral LVN caused horizontal nystagmus in the cat (Yules & Gault, 1966). McMasters et al. (1966) demonstrated projections from ventral LVN to the motor nucleus of the ipsilateral medial rectus and contralateral lateral rectus muscles in the monkey. These muscles would cause the eyes to move in the horizontal plane. Tarlov (1970) denied the presence of projections from LVN to eye muscle motor nuclei in the cat. However, Gacek (1971) found projections from ventral LVN to both the abducens nucleus and the dorso-lateral cell group of the ipsilateral oculomotor nucleus in the cat. The dorso-lateral cell group innervates the medial rectus muscle in this animal (Tarlov & Tarlov, 1971).

PAN was preserved after contralateral labyrinthectomy in 728. It seems likely that ventral LVN is not a major receiving area for primary afferents from the otolith organs responsible for PAN. Presumably the majority of these fibers enter rostral DVN. The separation of lesions which affect horizontal caloric nystagmus and PAN is somewhat against the conclusion of Money et al. (1965) and Nito et al. (1964, 1968) that PAN originates in the lateral semicircular canals.

The descending vestibular nucleus. On the basis of oculomotor and postural effects of lesions, DVN appears to be subdivided into a rostral and caudal part. A lesion of rostral DVN (717, Fig. 57 B) caused a marked head tilt to the ipsilateral side (Fig. 58, 717), contralateral horizontal rotatory spontaneous nystagmus, and a loss of positional effects on spontaneous nystagmus and PAN following contralateral labyrinthectomy. The loss of positional effects on spontaneous nystagmus and on PAN suggests that rostral DVN is directly concerned with processing information from the otolith organs for vestibulo-ocular reflexes. This agrees with the anatomical findings that rostral DVN receives primary vestibular afferents from the utricle (Stein & Carpenter, 1967). It is also consistent with data of Peterson (1970) that units in rostral DVN had the greatest sensitivity to lateral head tilt. There was relatively little influence of the caudal DVN lesion (Fig. 57 C) on spontaneous nystagmus and caloric responses, and PAN was preserved after contralateral labyrinthectomy. We would infer that caudal DVN is not a primary sensory receiving area for vestibulo-ocular information arising either in the semicircular canals or in the otolith organs.

The route by which activity from rostral DVN reaches the oculomotor nuclei is unclear. Pompeiano & Walberg (1957) showed that there were retrograde cell changes in rostral DVN after MLF lesions. On the other hand, little or no degeneration has been found in the ascending MLF or oculomotor nuclei after rostral DVN lesions in a number of studies (McMasters et al., 1966; Tarlov, 1970; Gacek, 1971). Another possible route for activity from rostral DVN to the eye muscle motor nuclei is through the cerebellum. Brodal & Torvik (1957) have shown that caudal DVN projects to the vestibulo-cerebellum and Angaut & Brodal (1967) that caudal DVN receives afferent projections from the nodulus and uvula. They suggest the existence of a loop between the nodulus and uvula and cau

Fig. 58. Pictures of head position and body posture after lesion and in some monkeys after contralateral labyrinthectomy. The lesions are all shown on the left side. The monkeys are identified by numbers and are positioned over the left vestibular nuclear complex in the approximate area of the destruction. The small arrows indicate the direction of the spontaneous nystagmus and the small numbers the number of days the nystagmus was present in light. The heavy arrows point to the head position and body posture after contralateral (right) labyrinthectomy. 734 had gaze nystagmus to the left for 28 days and temporary spontaneous nystagmus to the right (shown by the arrow in parentheses). 729 first had a left labyrinthectomy and then the right labyrinth was destroyed.

dal DVN The cerebellum in turn has direct pathways to vertical and vertical rotatory eye movers (Carpenter & Strominger 1964 Highstein 1971 1973 a Highstein et al., 1971)

Apogeotropic direction-changing positional nystagmus was striking after caudal DVN destruction in 712. However it was still possible to produce nystagmus to either side during PAN I after the contralateral labyrinth had been destroyed Thus caudal DVN could not be essential for preservation of PAN It is possible that caudal DVN plays a role in modulating or inhibiting otolith-ocular reflexes

There was also evidence for a functional separation of rostral and caudal DVN from their different effects on posture The monkey with a rostral DVN lesion had an ipsilateral falling tendency and head tilt (Fig 58 717) Its neck muscles appeared to be strongly affected After a caudal DVN lesion there was severe dysequilibrium which appeared to be more closely related to changes in lumbar and hindlimb musculature (Fig. 58 712) Similar postural changes were described by Carpenter et al (1960) in the cat after DVN destruction

Present knowledge is insufficient to explain the different postural effects of rostral and caudal DVN lesions or of any DVN lesions for that matter According to anatomical studies DVN does not project directly to the spinal cord (Carpenter 1960 Carpenter et al 1960 Nyberg-Hansen & Mascitti 1964 Nyberg Hansen 1964) However Wilson et al (1967b) and Kawai et al. (1969) found cells in medial DVN with axons which descended to the spinal cord so that presumably such connections exist Other possibilities are that the postural changes were mediated over multi-synaptic pathways or through the cerebellum. Spino-vestibular projections to DVN only reach the most caudal portions (Pompeiano & Brodal 1957 b Brodal & Angaut, 1967) This may mean that the same type of organization is present in DVN as in LVN (Brodal et al 1962) That is parts of LVN which receive primary vestibular afferents (ventral LVN) project more heavily to the cervical spinal cord while portions which receive spinal afferents (dorsal LVN) project more heavily to the lumbo-sacral cord

The superior vestibular nucleus It is generally assumed that oculomotor function is predominantly represented in SVN The striking postural changes in 724 (Fig 58) indicate that this nucleus may also exert some control over body posture The pathways over which this control might be mediated are unknown

The horizontal component of induced caloric nystagmus was preserved after total SVN destruction Therefore SVN could not be essential for production of horizontal caloric nystagmus On the other hand eye movements induced by SVN stimulation (Tokumasu et al 1969) and spontaneous nystagmus following SVN destruction were in planes parallel to the plane of the ipsilateral anterior semicircular canal or the contralateral posterior canal This suggests that SVN plays a role in mediating activity between the anterior canals and the eye muscle motor nuclei. Downward eye movements were never induced by SVN stimulation (Tokumasu et al 1969).

The oculomotor projections of SVN are in accord with this hypothesis. In the monkey the projection of SVN is ipsilateral (McMasters et al. 1966) and is heaviest to motoneurons innervating the contralateral *superior oblique* and the ipsilateral inferior rectus muscles. Projections from SVN only carry inhibition (Highstein & Ito 1971 Highstein et al 1971 Precht & Baker 1972) If the ipsilateral inferior rectus and contralateral superior oblique muscles are inhibited the ipsilateral eye moves up and the contralateral eye moves up and extorts. These are exactly the eye movements induced by stimulation of the ipsilateral anterior canal nerve (Cohen et al 1964 Suzuki et al. 1964 Suzuki & Cohen 1964) or of SVN (Tokumasu et al 1969) and are just the reverse of the slow phases

to the cervical spinal cord (Wilson et al. 1968 *a*) in the medial vestibulo-spinal tract (Nyberg-Hansen, 1964 1966) These afferents mainly mediate inhibition onto cervical motoneurons (Wilson & Yoshida 1969 *a*) Excitatory inputs on the same motoneurons come from LVN via the lateral vestibulo-spinal tract (Wilson & Yoshida, 1969 *b*) Head tilt was stronger after nerve root destruction in 728 which caused degeneration in parts of LVN which project to the cervical spinal cord (Pompeiano & Brodal 1957 *a*) This may indicate that a loss of excitation causes more manifest postural changes than a loss of inhibition.

With one exception none of the monkeys had positional nystagmus after MVN lesions and PAN was preserved after contralateral labyrinthectomy It does not appear that MVN is of primary importance in processing information in otolith-ocular reflex arcs

Anatomical findings suggest that there is a functional separation between rostral and central MVN Rostral MVN together with SVN is a major terminus of afferent fibers from the semicircular canals (Stein & Carpenter 1967 Gacek, 1969) This region sends axons to eye muscle motor nuclei through the MLF and commissural fibers (McMasters et al 1966 Tarlov 1970 Gacek 1971). Central and caudal MVN does not receive primary afferent vestiblar fibers nor does it project to the oculomotor system Angaut & Brodal (1967) have also separated rostral and caudal MVN based on the distribution of fibers from the flocculus and nodulus The separation of rostral and central MVN is in accord with results of caloric testing Monkeys with lesions of rostral MVN exhibited perverted caloric nystagmus This did not occur after central MVN destruction

There are both excitatory and inhibitory projections from rostral MVN to eye muscle motor nuclei (Baker et al 1969 Highstein et al. Highstein 1971 1973 *a* 1973 *b* Precht & Baker 197? Richter & Precht 1968) MVN also sends axons to the contralateral vestibular nuclei in the commissural system which are primarily inhibitory (Ladpli & Brodal 1968 Shimazu & Precht 1966) The pattern of vestibulo-oculomotor projections from MVN is complex and is not related solely or predominantly to eye movements in any single plane (McMasters et al. 1966 Tarlov 1970 Gacek, 1971)

In view of the heavy input from the semicircular canals it is surprising that the spontaneous nystagmus was not stronger and that the changes in caloric nystagmus were not more protean after the rostral MVN lesions The main changes in nystagmus were an enhancement of vertical components (perverted nystagmus) and loss of the horizontal component of nystagmus induced by hot caloric stimulation i.e by an increase of activity in the lateral canal nerve It is possible that the MVN lesions were too small to cause greater effects. On the other hand portions of the nuclei which were destroyed in 4 animals (Fig 43 Fig 44) are just those parts of MVN which receive primary afferents from the semicircular canals (Stein & Carpenter 1967 Gacek, 1969) and a stronger effect on caloric nystagmus induced by cold stimulation would have been expected

The horizontal components of nystagmus induced by ipsilateral hot stimulation were lost for more than 3 months in 588 Despite this the horizontal components induced by cold caloric stimulation were unaffected. This suggests that rostral MVN may be important in generating or controlling horizontal slow phases induced by increasing activity in the ampullary nerve from the lateral canal, although the nature of this control is still unclear

Perverted caloric nystagmus in 700 701 and 715 after dorso-rostral MVN lesions was similar to that found in 724 after SVN destruction (Fig. 47) In 588 after more extensive rostral MVN damage the perversion was more severe and was induced by ipsilateral hot as well as by contralateral hot and cold stimulation. This suggests that the enhanced vertical caloric

of spontaneous nystagmus after SVN destruction Gacek (1971) also found an entirely ipsilateral projection from SVN in the cat If sites of termination in the oculomotor nucleus are interpreted according to findings of Tarlov & Tarlov (1971) then mainly the contralateral superior oblique and the ipsilateral inferior rectus and inferior oblique receive projections from SVN in this animal as well

SVN cannot be the only part of the vestibular nuclei responsible for eye movements in anterior canal planes since it was still possible to evoke vertical caloric nystagmus by bilateral simultaneous stimulation after total SVN destruction Moreover Tokumasu & Goto (unpub results) destroyed SVN in the cat and were still able to induce upward rotatory eye movements from stimulation of the ipsilateral anterior canal nerve Presumably the pathway carrying excitatory activity from the anterior canals goes through other parts of the vestibular nuclei

Enhancement of vertical rotatory components of caloric nystagmus induced by stimulation of the contralateral ear was striking after SVN and MVN lesions As noted in the Section on Interpretation of Vertical Caloric Responses the horizontal component of caloric nystagmus predominates in normal animals even though the anterior canal is concommitantly stimulated The plane of the perverted nystagmus was parallel to the plane of the anterior canal on the side which was calorically stimulated The most likely explanation for the perverted nystagmus is that there was a loss of suppression of anterior canal responses From the lesion data it seems likely that this suppression originated in SVN and MVN and projected to the vestibular nuclei on the contralateral side After SVN and MVN lesions this suppression was lost and the dysinhibited response of the anterior canals appeared

As noted in the Introduction Ladpli & Brodal (1968) have shown that vestibular commissural fibers originate in SVN and MVN and cross the brain stem to distribute to the four vestibular nuclei on the opposite side The vestibular commissural system mediates inhibition in most of its projections (Shimazu & Precht 1966 Wilson et al 1968 b Kasahara et al 1968 Mano et al 1968) Therefore the physiological and anatomical substrate for crossed inhibition exists although it has not been tied to suppression of anterior canal activity Perverted caloric responses due to anterior canal excitation after SVN lesions would be another line of evidence which suggests that SVN is closely related to anterior canal function or to representation of eye movements in planes of space parallel to the anterior canal

Although SVN receives primary vestibular afferents mainly from the semicircular canals, positional nystagmus was present after SVN lesions This shows that SVN must also play a role in mediating or modulating otolith-ocular reflexes Positional nystagmus after SVN lesions could not have come from interruption of primary afferents from the utricle and saccule since there are few (Stein & Carpenter 1967) or none of these axons which terminate in SVN (Gacek 1969) On the other hand SVN receives axons from the flocculus the nodulus and the uvula (Angaut & Brodal 1967 Voogd 1964) as well as from the fastigial nucleus (Walberg et al 1962) It seems likely that the interruption of afferent cerebello-vestibular fibers in addition to destruction of SVN itself was important in causing the positional nystagmus found in monkeys with SVN lesions As noted there is also a close relationship between caudal DVN and the nodulus and uvula and positional nystagmus was also present after lesions of these structures

The medial vestibular nucleus The role of MVN in maintenance of posture or production of eye movements is not elucidated by our findings Postural abnormalities were minimal after lesions of either rostral or central MVN (Fig 57 D G Fig 58 715 732) These portions of MVN send afferents

to the cervical spinal cord (Wilson et al 1968 *a*) in the medial vestibulo-spinal tract (Nyberg-Hansen 1964 1966). These afferents mainly mediate inhibition onto cervical motoneurons (Wilson & Yoshida 1969 *a*) Excitatory inputs on the same motoneurons come from LVN via the lateral vestibulo-spinal tract (Wilson & Yoshida 1969 *b*) Head tilt was stronger after nerve root destruction in 728 which caused degeneration in parts of LVN which project to the cervical spinal cord (Pompeiano & Brodal, 1957 *a*) This may indicate that a loss of excitation causes more manifest postural changes than a loss of inhibition

With one exception none of the monkeys had positional nystagmus after MVN lesions and PAN was preserved after contralateral labyrinthectomy It does not appear that MVN is of primary importance in processing information in otolith-ocular reflex arcs

Anatomical findings suggest that there is a functional separation between rostral and central MVN Rostral MVN together with SVN is a major terminus of afferent fibers from the semicircular canals (Stein & Carpenter 1967 Gacek 1969) This region sends axons to eye muscle motor nuclei through the MLF and commissural fibers (McMasters et al 1966 Tarlov 1970 Gacek, 1971). Central and caudal MVN does not receive primary afferent vestiblar fibers nor does it project to the oculomotor system. Angaut & Brodal (1967) have also separated rostral and caudal MVN based on the distribution of fibers from the flocculus and nodulus The separation of rostral and central MVN is in accord with results of caloric testing. Monkeys with lesions of rostral MVN exhibited perverted caloric nystagmus. This did not occur after central MVN destruction

There are both excitatory and inhibitory projections from rostral MVN to eye muscle motor nuclei (Baker et al 1969 Highstein et al. Highstein 1971 1973 *a* 1973 *b* Precht & Baker 197? Richter & Prect 1968) MVN also sends axons to the contralateral vestibular nuclei in the commissural system which are primarily inhibitory (Ladpli & Brodal 1968 Shimazu & Precht, 1966) The pattern of vestibulo-oculomotor projections from MVN is complex and is not related solely or predominantly to eye movements in any single plane (McMasters et al 1966 Tarlov 1970 Gacek, 1971)

In view of the heavy input from the semicircular canals it is surprising that the spontaneous nystagmus was not stronger and that the changes in caloric nystagmus were not more protean after the rostral MVN lesions The main changes in nystagmus were an enhancement of vertical components (perverted nystagmus) and loss of the horizontal component of nystagmus induced by hot caloric stimulation i e by an increase of activity in the lateral canal nerve It is possible that the MVN lesions were too small to cause greater effects On the other hand portions of the nuclei which were destroyed in 4 animals (Fig. 43 Fig. 44) are just those parts of MVN which receive primary afferents from the semicircular canals (Stein & Carpenter 1967 Gacek, 1969) and a stronger effect on caloric nystagmus induced by cold stimulation would have been expected.

The horizontal components of nystagmus induced by ipsilateral hot stimulation were lost for more than 3 months in 588 Despite this the horizontal components induced by cold caloric stimulation were unaffected. This suggests that rostral MVN may be important in generating or controlling horizontal slow phases induced by increasing activity in the ampullary nerve from the lateral canal although the nature of this control is still unclear

Perverted caloric nystagmus in 700 701 and 715 after dorso-rostral MVN lesions was similar to that found in 724 after SVN destruction (Fig. 47) In 588 after more extensive rostral MVN damage the perversion was more severe and was induced by ipsilateral hot as well as by contralateral hot and cold stimulation. This suggests that the enhanced vertical caloric

of spontaneous nystagmus after SVN destruction Gacek (1971) also found an entirely ipsilateral projection from SVN in the cat If sites of termination in the oculomotor nucleus are interpreted according to findings of Tarlov & Tarlov (1971) then mainly the contralateral superior oblique and the ipsilateral inferior rectus and inferior oblique receive projections from SVN in this animal as well

SVN cannot be the only part of the vestibular nuclei responsible for eye movements in anterior canal planes since it was still possible to evoke vertical caloric nystagmus by bilateral simultaneous stimulation after total SVN destruction Moreover Tokumasu & Goto (unpub results) destroyed SVN in the cat and were still able to induce upward rotatory eye movements from stimulation of the ipsilateral anterior canal nerve Presumably the pathway carrying excitatory activity from the anterior canals goes through other parts of the vestibular nuclei

Enhancement of vertical rotatory components of caloric nystagmus induced by stimulation of the contralateral ear was striking after SVN and MVN lesions As noted in the Section on Interpretation of Vertical Caloric Responses the horizontal component of caloric nystagmus predominates in normal animals even though the anterior canal is concommitantly stimulated The plane of the perverted nystagmus was parallel to the plane of the anterior canal on the side which was calorically stimulated The most likely explanation for the perverted nystagmus is that there was a loss of suppression of anterior canal responses From the lesion data it seems likely that this suppression originated in SVN and MVN and projected to the vestibular nuclei on the contralateral side After SVN and MVN lesions this suppression was lost and the dysinhibited response of the anterior canals appeared

As noted in the Introduction Ladpli & Brodal (1968) have shown that vestibular commissural fibers originate in SVN and MVN and cross the brain stem to distribute to the four vestibular nuclei on the opposite side The vestibular commissural system mediates inhibition in most of its projections (Shimazu & Precht 1966 Wilson et al 1968 *b* Kasahara et al 1968 Mano et al 1968) Therefore the physiological and anatomical substrate for crossed inhibition exists although it has not been tied to suppression of anterior canal activity Perverted caloric responses due to anterior canal excitation after SVN lesions would be another line of evidence which suggests that SVN is closely related to anterior canal function or to representation of eye movements in planes of space parallel to the anterior canal

Although SVN receives primary vestibular afferents mainly from the semicircular canals positional nystagmus was present after SVN lesions This shows that SVN must also play a role in mediating or modulating otolith ocular reflexes Positional nystagmus after SVN lesions could not have come from interruption of primary afferents from the utricle and saccule since there are few (Stein & Carpenter 1967) or none of these axons which terminate in SVN (Gacek 1969) On the other hand SVN receives axons from the flocculus the nodulus and the uvula (Angaut & Brodal 1967 Voogd 1964) as well as from the fastigial nucleus (Walberg et al 1962). It seems likely that the interruption of afferent cerebello-vestibular fibers in addition to destruction of SVN itself was important in causing the positional nystagmus found in monkeys with SVN lesions As noted there is also a close relationship between caudal DVN and the nodulus and uvula and positional nystagmus was also present after lesions of these structures

The medial vestibular nucleus The role of MVN in maintenance of posture or production of eye movements is not elucidated by our findings Postural abnormalities were minimal after lesions of either rostral or central MVN (Fig 57 D G Fig 58 715 732) These portions of MVN send afferents

Spontaneous nystagmus

Disconjugate defects such as are found after MLF lesions (Bender & Weinstein, 1944 Carpenter & McMasters 1963 Cohen, 1971) were not present in any of the animals of this series. Therefore disconjugate defects if present, are a sign of lesions outside the vestibular nuclei. Similarly gaze nystagmus was not prominent after lesions of the vestibular complex

Spontaneous nystagmus which followed left vestibular nuclei lesions was horizontal rotatory upward rotatory and pure rotatory in character Nystagmus with a downward component was not initially observed in any of the animals with vestibular nuclei lesions although in several animals the positional nystagmus was downward during the recovery course. The reason for the absence of downward spontaneous nystagmus is not known. In animals with left-sided lesions rotatory components were counterclockwise (Fig. 58) This is just opposite to the rotatory components of nystagmus induced by stimulation of the vestibular nuclei on the left side (Tokumasu et al 1969)

The horizontal component of the spontaneous nystagmus was contralateral after lesions of the nerve root and of caudal lateral parts of the vestibular nuclei After SVN and rostral MVN lesions on the other hand the horizontal component of the spontaneous nystagmus was ipsilateral. Thus is just the reverse of nystagmus induced by electrical stimulation of these parts of the vestibular nuclei i.e to the ipsilateral side with lateral stimulation and to the contralateral side with medial stimulation (see Figure 6 A of Tokumasu et al., 1969) Pure horizontal or vertical nystagmus was not present in any of the animals with vestibular nuclei lesions Bender (1960) has noted that vertical nystagmus in the mid-sagittal plane is most commonly associated with midline or bilateral brainstem lesions

The reversal in direction of spontaneous nystagmus from contralateral to ipsilateral side was noted in the EOG during the recovery course in monkeys with lesions of the root entry zone and rostral DVN as well as after unilateral labyrinthectomy Igarashi et al (1970) also found a change in the direction of falling on a rail test in squirrel monkeys after unilateral labyrinthectomy

Positional nystagmus

Positional nystagmus is associated with cerebellar lesions (Nylén 1931 1950 Spiegel & Scala, 1942 Fernández, 1960 Fernández & Fredrickson 1964 Cohen et al 1969 Cohen & Highstein 1972) vestibular nuclei lesions and lesions of cerebello-vestibular connections (727) Animals with lesions in two parts of the vestibular nuclei had direction-changing positional nystagmus After caudal DVN destruction there was apogeotropic direction-changing positional nystagmus which was mainly horizontal It was to the left with the right side down and to the right with the left side down. We have not observed apogeotropic or antigravity positional nystagmus after labyrinthectomy or after other vestibular nuclei lesions but it has been produced by lesions of the cerebellar nuclei (Cohen et al. 1969 Cohen & Highstein, 1972)

In contrast positional nystagmus associated with lesions of SVN had strong rotatory components, and the direction of rotation reversed in 722 and 724 when the head was put into different positions After flocculus lesions there is rotatory positional nystagmus in the coronal plane for about 1 week (Cohen & Takemori, 1973) This is of interest in view of the heavy projections from the flocculus to SVN Rotatory positional nystagmus is found in patients with benign paroxysmal vertigo However this nystagmus reverses when the patient is brought from the supine to the upright position, not when the head is to the left or right as in 724 or 722.

Direction-fixed positional nystagmus was also commonly induced in animals with vestibular nuclei lesions. It usually occurred in conjunction with the spontaneous nystag-

*nystagmus was not only due to a loss of in*hibition originating in SVN but probably also to an intrinsic effect of MVN destruction on the perversion as well

The medullary reticular formation Evidence which suggests that the dorsal medullary reticular formation may play a role in ocular function is limited However Hyde & Eliasson (1957) found two areas in the brain stem of the cat from which horizontal eye movements could be induced by electrical stimulation One was *the tegmentum of the* pons which is known to be important for production of horizontal gaze (Bender & Shanzer 1964 Cohen 1971) The other was more caudal in the medulla When this area was destroyed strong directional preponderance of OKN and loss of OKAN was produced Further studies are needed to elucidate the extent of this region and its role in producing eye movements

B CLINICAL IMPLICATIONS

Changes in Posture

Only simple postural testing was done after *vestibular nuclei lesions* and disturbances in posture were probably underestimated The relative intensity of postural imbalance and of spontaneous nystagmus varied according to the parts of the vestibular nuclei which were damaged *Nevertheless the direction of the* falling tendency and head tilt following unilateral vestibular nuclei lesions was in accordance with the direction of the slow phases of spontaneous nystagmus This is shown in Figs 57 & 58 Monkeys with *lesions of lateral or* caudal parts of the vestibular nuclei (728 717 712) or of the peripheral apparatus (729 707) had head tilts to the ipsilateral side and spon*taneous nystagmus to* the contralateral side (ipsilateral slow phases) 724 and 715 with lesions of SVN and rostral MVN had some contralateral head tilt and an ipsilateral component to their spontaneous nystagmus 722 *with an intermediate lesion* had no head tilt

The coincidence of the direction of head tilt and falling tendency with the direction of the slow phases of spontaneous nystagmus after *vestibular nuclei lesions* can be contrasted to that observed after lesions outside the vestibular *nuclei Both the head tilt and quick* phases of nystagmus were directed to the ipsilateral side after *dorsal medullary reticular* formation lesions (734) and to the contralateral side after pontine reticular formation *lesions* (Cohen *et al* 1968) *These* differences in direction of postural deviation and spontaneous nystagmus may be of use in separating lesions in and around the vestibular nuclei Although coincidence of the direction of slow phases and falling tendency cannot be used to separate central from peripheral *vestibular lesions a falling tendency* in the same direction as the quick phases of nystagmus would appear to point to a lesion involving parts of the central nervous system outside the vestibular nuclei

The most severe disturbances of posture were noted after DVN lesions although dysequilibrium after SVN destruction was also strong Disturbances of equilibrium following lesions of the root entry zone were some*what weaker* Despite the intimate relationship between MVN and the cervical spinal cord little change in posture was manifest after either rostral or central MVN destruction

Postural deficits due to unilateral vestibular lesions showed rapid attenuation within one month in all animals and in most monkeys there was only a minimal effect of subsequent destruction of the contralateral labyrinth *The contralateral labyrinthectomy* also had a smaller effect on posture than the initial labyrinthectomy in 707 and 729 Only in 715 was there a strong head tilt after contralateral labyrinthectomy (Fig 58) and it persisted unchanged until sacrifice 40 days later Mechanisms to compensate for the head tilt after contralateral labyrinthectomy appeared to be disturbed in this animal

Spontaneous nystagmus

Disconjugate defects such as are found after MLF lesions (Bender & Weinstein 1944 Carpenter & McMasters 1963 Cohen, 1971) were not present in any of the animals of this series Therefore disconjugate defects if present, are a sign of lesions outside the vestibular nuclei. Similarly gaze nystagmus was not prominent after lesions of the vestibular complex.

Spontaneous nystagmus which followed left vestibular nuclei lesions was horizontal rotatory upward rotatory and pure rotatory in character Nystagmus with a downward component was not initially observed in any of the animals with vestibular nuclei lesions although in several animals the positional nystagmus was downward during the recovery course. The reason for the absence of downward spontaneous nystagmus is not known. In animals with left-sided lesions rotatory components were counterclockwise (Fig. 58) This is just opposite to the rotatory components of nystagmus induced by stimulation of the vestibular nuclei on the left side (Tokumasu et al 1969)

The horizontal component of the spontaneous nystagmus was contralateral after lesions of the nerve root and of caudal lateral parts of the vestibular nuclei After SVN and rostral MVN lesions on the other hand the horizontal component of the spontaneous nystagmus was ipsilateral. This is just the reverse of nystagmus induced by electrical stimulation of these parts of the vestibular nuclei i.e to the ipsilateral side with lateral stimulation and in the contralateral side with medial stimulation (see Figure 6 A of Tokumasu et al. 1969). Pure horizontal or vertical nystagmus was not present in any of the animals with vestibular nuclei lesions Bender (1960) has noted that vertical nystagmus in the mid-sagittal plane is most commonly associated with midline or bilateral brainstem lesions.

The reversal in direction of spontaneous nystagmus from contralateral to ipsilateral side was noted in the EOG during the recovery course in monkeys with lesions of the root entry zone and rostral DVN as well as after unilateral labyrinthectomy Igarashi et al (1970) also found a change in the direction of falling on a rail test in squirrel monkeys after unilateral labyrinthectomy

Positional nystagmus

Positional nystagmus is associated with cerebellar lesions (Nylén 1931 1950 Spiegel & Scala, 1942 Fernández, 1960 Fernández & Fredrickson 1964 Cohen et al 1969 Cohen & Highstein 1972) vestibular nuclei lesions and lesions of cerebello-vestibular connections (727) Animals with lesions in two parts of the vestibular nuclei had direction-changing positional nystagmus. After caudal DVN destruction, there was apogeotropic direction-changing positional nystagmus which was mainly horizontal It was to the left with the right side down and to the right with the left side down. We have not observed apogeotropic or antigravity positional nystagmus after labyrinthectomy or after other vestibular nuclei lesions but it has been produced by lesions of the cerebellar nuclei (Cohen et al 1969 Cohen & Highstein 1972)

In contrast positional nystagmus associated with lesions of SVN had strong rotatory components, and the direction of rotation reversed in 722 and 724 when the head was put into different positions After flocculus lesions there is rotatory positional nystagmus in the coronal plane for about 1 week (Cohen & Takemori, 1973) This is of interest in view of the heavy projections from the flocculus to SVN Rotatory positional nystagmus is found in patients with benign paroxysmal vertigo However this nystagmus reverses when the patient is brought from the supine to the upright position not when the head is to the left or right as in 724 or 722.

Direction-fixed positional nystagmus was also commonly induced in animals with vestibular nuclei lesions It usually occurred in conjunction with the spontaneous nystag

nystagmus was not only due to a loss of in hibition originating in SVN but probably also to an intrinsic effect of MVN destruction on the perversion as well

The medullary reticular formation Evi dence which suggests that the dorsal medul lary reticular formation may play a role in ocular function is limited However Hyde & Eliasson (1957) found two areas in the brain stem of the cat from which horizontal eye movements could be induced by electrical stimulation One was the tegmentum of the pons which is known to be important for pro duction of horizontal gaze (Bender & Shanzer 1964 Cohen 1971) The other was more caudal in the medulla When this area was destroyed strong directional preponderance of OKN and loss of OKAN was produced Further studies are needed to elucidate the extent of this region and its role in producing eye movements

B CLINICAL IMPLICATIONS

Changes in Posture

Only simple postural testing was done after vestibular nuclei lesions and disturbances in posture were probably underestimated The relative intensity of postural imbalance and of spontaneous nystagmus varied according to the parts of the vestibular nuclei which were damaged Nevertheless the direction of the falling tendency and head tilt following uni lateral vestibular nuclei lesions was in accord ance with the direction of the slow phases of spontaneous nystagmus This is shown in Figs 57 & 58 Monkeys with lesions of lateral or caudal parts of the vestibular nuclei (728 717 712) or of the peripheral apparatus (729 707) had head tilts to the ipsilateral side and spon taneous nystagmus to the contralateral side (ipsilateral slow phases) 724 and 715 with lesions of SVN and rostral MVN had some contralateral head tilt and an ipsilateral com ponent to their spontaneous nystagmus 722 with an intermediate lesion had no head tilt.

The coincidence of the direction of head tilt and falling tendency with the direction of the slow phases of spontaneous nystagmus after vestibular nuclei lesions can be contrasted to that observed after lesions outside the vestib ular nuclei Both the head tilt and quick phases of nystagmus were directed to the ipsilateral side after dorsal medullary retic ular formation lesions (734) and to the con tralateral side after pontine reticular for mation lesions (Cohen et al 1968) These differences in direction of postural deviation and spontaneous nystagmus may be of use in separating lesions in and around the vestibular nuclei Although coincidence of the direction of slow phases and falling tendency cannot be used to separate central from peripheral vestibular lesions a falling tendency in the same direction as the quick phases of nystag mus would appear to point to a lesion in volving parts of the central nervous system outside the vestibular nuclei

The most severe disturbances of posture were noted after DVN lesions although dys equilibrium after SVN destruction was also strong Disturbances of equilibrium follow ing lesions of the root entry zone were some what weaker Despite the intimate relation ship between MVN and the cervical spinal cord little change in posture was manifest after either rostral or central MVN destruc tion

Postural deficits due to unilateral vestib ular lesions showed rapid attenuation within one month in all animals and in most mon keys there was only a minimal effect of sub sequent destruction of the contralateral laby rinth The contralateral labyrinthectomy also had a smaller effect on posture than the initial labyrinthectomy in 707 and 729 Only in 715 was there a strong head tilt after contralateral labyrinthectomy (Fig 58) and it persisted unchanged until sacrifice 40 days later Mechanisms to compensate for the head tilt after contralateral labyrinthectomy ap peared to be disturbed in this animal

This emphasizes the clinical importance of both hot and cold caloric stimulation when investigating patients with suspected vestibular nuclei lesions.

Optokinetic nystagmus

The loss of OKAN and changes in OKN after destruction of the vestibular apparatus (Cohen et al 1973) are of interest because they demonstrate the close relationship between the vestibular and visual systems in producing eye movements. In agreement with this, there was directional preponderance of OKN after unilateral vestibular nuclei lesions. This was always associated with spontaneous nystagmus and with directional preponderance of caloric nystagmus with positional nystagmus or with changes in PAN. OKN was less strongly affected than caloric nystagmus when lesions were inside the vestibular nuclei.

In contrast, lesions of the dorsal medullary reticular formation (586 734) and mesencephalic reticular formation (MRF) (Komatsuzaki et al. 1972) cause stronger changes in OKN than in caloric nystagmus. After MRF lesions there is frequently ipsilateral gaze preference and spontaneous nystagmus and an inability to generate contralateral OKN. Caloric nystagmus is relatively normal in these animals. Lesions of the paramedian zone of the pontine reticular formation (PPRF) are associated with an inability to produce quick phases of high velocity to the ipsilateral side (Cohen et al. 1968 Cohen & Henn 1972). PPRF lesions produce conjugate gaze paralysis which affects all types of nystagmus similarly regardless of how they were induced. Lesions in more distal parts of oculomotor pathways such as MLF lesions which produce paralysis of adduction (Bender & Shanzer 1964) or motor nuclei or nerve lesions also affect all types of nystagmus similarly.

mus but at later stages in the recovery course *could occur alone* The observed nystagmus was similar in animals with labyrinthectomy or with lesions of the root entry zone In these monkeys (707 729 728) it was predominantly contralateral horizontal with the ipsilateral side down and rotatory with the contralateral side down The upside down position was most sensitive for eliciting positional nystagmus during recovery This is analogous to the head-hanging positions used in testing humans

Caloric nystagmus

Canal paresis was not found after SVN central and caudal DVN or rostral and central MVN lesions but was present after damage of the vestibular nerve at the root *entry zone It was characterized by a decrease* in the velocity of slow phases of nystagmus induced by cold and hot stimulation of the ipsilateral ear Duration of nystagmus was much less affected in animals which had canal paresis It has been suggested that the way in which duration and maximum slow phase velocity of caloric nystagmus are affected by vestibular lesions may give some idea as to the site of damage (Stahle 1956 Aschan & Stahle 1956) After vestibular neuronitis changes are mainly in parameters related to *slow phase velocity and duration of nystagmus* is affected only to a lesser extent In contrast disease of the peripheral labyrinth such as Menière s disease appears to affect all parameters of nystagmus similarly (Aschan & Stahle 1956)

It has been assumed that vestibular neuronitis is due to vestibular nerve damage but there has been no anatomical verification of this to our knowledge The findings in 728 show that lesions which partially destroy the nerve or nerve roots reproduce this constellation of signs This seems reasonable *since duration of nystagmus is related* to the time course of cupula deflection which in turn is dependent on the elasticity of the cupula. This would not be affected by nerve lesions On the other hand peripheral lesions which affect the cupula or hair cells would be expected to reduce all aspects *of the response* of the peripheral end organ

In animals with nerve root lesions stronger caloric stimuli i e those further away from body temperature did not recruit stronger caloric nystagmus If weaker stimuli were used the caloric nystagmus had nearly the same intensity from the intact as from the lesion side and *differences* in intensity of the induced response could be easily overlooked This is just the reverse of the response to weak and strong caloric stimulation after lesions of the labyrinth itself (Litton & *McCabe 1966 Steffen* et al *1970 Torok* 1970 Mendel 1971)

Every animal with spontaneous nystagmus *had some indication of directional preponderance* in the caloric test It was not of value *in differentiating the side or locus of the* lesion The strong directional preponderance in 734 suppressed caloric nystagmus in one direction and mimicked a loss of recruitment *although there was no canal paresis in this animal In 728 and 727 however no recruitment* was observed even after reversal of the spontaneous nystagmus by contralateral labyrinthectomy

Perverted caloric nystagmus i e nystagmus *with enhanced vertical components* was present after SVN lesions or after rostral MVN lesions Similar perversion has been found after brain stem lesions (Stroud et al 1971) after interruption of the vestibular commissural fibers by midline section (Cohen & de Jong unpublished data) or after cerebral hemidecortication (Pasik et al 1960) It was not *found after flocculus lesions or lesions of the* reticular formation of the pons (Cohen et al 1968) or mesencephalon (Komatsuzaki et al 1972) It is important to note that in some animals perverted caloric nystagmus was induced only by hot caloric stimulation on the side contralateral to the lesion *If both hot* and cold stimulation were not used in these monkeys *the findings would have been missed*

This emphasizes the clinical importance of both hot and cold caloric stimulation when investigating patients with suspected vestibular nuclei lesions

Optokinetic nystagmus

The loss of OKAN and changes in OKN after destruction of the vestibular apparatus (Cohen et al 1973) are of interest because they demonstrate the close relationship between the vestibular and visual systems in producing eye movements In agreement with this there was directional preponderance of OKN after unilateral vestibular nuclei lesions This was always associated with spontaneous nystagmus and with directional preponderance of caloric nystagmus with positional nystagmus or with changes in PAN OKN was less strongly affected than caloric nystagmus when lesions were inside the vestibular nuclei.

In contrast lesions of the dorsal medullary reticular formation (586 734) and mesencephalic reticular formation (MRF) (Komatsuzaki et al 1972) cause stronger changes in OKN than in caloric nystagmus. After MRF lesions there is frequently ipsilateral gaze preference and spontaneous nystagmus and an inability to generate contralateral OKN Caloric nystagmus is relatively normal in these animals Lesions of the paramedian zone of the pontine reticular formation (PPRF) are associated with an inability to produce quick phases of high velocity to the ipsilateral side (Cohen et al 1968 Cohen & Henn 1972) PPRF lesions produce conjugate gaze paralysis which affects all types of nystagmus similarly regardless of how they were induced. Lesions in more distal parts of oculomotor pathways such as MLF lesions which produce paralysis of adduction (Bender & Shanzer 1964) or motor nuclei or nerve lesions also affect all types of nystagmus similarly

11 Conclusions

(1) Changes in body posture and in vestibulo-ocular reflexes were studied in monkeys after lesions of the vestibular nuclei and the peripheral vestibular apparatus Based on oculomotor and postural changes after vestibular nuclei lesions the vestibular nuclei were subdivided into separate areas These included ventral LVN dorsal LVN rostral DVN caudal DVN SVN rostral MVN and central caudal MVN

(2) Head tilt and falling tendency were to the ipsilateral side after lesions of lateral or caudal parts of the vestibular nuclei or after lesions of the labyrinth They were to the contralateral side after SVN or rostral MVN lesions Postural changes after central MVN lesions were slight The strongest postural effects were produced by lesions of caudal DVN

(3) Quick phases of nystagmus were not primarily affected by vestibular nuclear lesions All changes in eye movements were conjugate and disconjugate defects similar to those observed after MLF lesions were not produced by unilateral vestibular nuclei destruction

(4) Spontaneous nystagmus was commonly found after vestibular nuclei lesions It was of short duration in light but could persist in darkness for much longer periods of time The direction of the slow phases of spontaneous nystagmus agreed with the direction of the postural change in each of the animals Reversal of spontaneous nystagmus during the recovery course was also noted

(5) Direction fixed positional nystagmus was produced by labyrinthectomy and by lesions of the root entry zone and rostral DVN Positional effects on spontaneous nystagmus were lost after rostral DVN lesion and contralateral labyrinthectomy This finding is in accord with anatomic studies which indicate that rostral DVN is a primary receiving area for activity arising in the otolith organs

(6) Horizontal geotropic direction-changing positional alcohol nystagmus (PAN) was induced to both sides after unilateral labyrinthectomy PAN was lost after bilateral labyrinthectomy or after destruction of rostral DVN and the contralateral labyrinth The rostral DVN lesion had the same effect on positional nystagmus as on PAN This suggests that activity responsible for PAN arises mainly in the otolith organs not in the lateral semicircular canals and is mediated through rostral DVN

(7) Apogeotropic direction-changing positional nystagmus of the type commonly associated with central vestibular lesions cerebellar lesions or the second phase of positional alcohol nystagmus (PAN II) was found after caudal DVN lesion Rotatory direction-changing positional nystagmus was produced by SVN lesions Both caudal DVN and SVN have prominent vestibulo-cerebellar or cerebello-vestibular projections and positional nystagmus is produced by lesions of portions of the cerebellum where these projections originate or end The data support the hypothesis that the cerebellum plays an important role in controlling or mediating utriculo-ocular or sacculo-ocular reflex arcs

(8) Canal paresis i e a reduction in the response of the ipsilateral ear to cold or hot caloric stimulation and a loss of recruitment was found when the root entry zone was damaged After root entry zone lesions there was little effect on the duration of induced nystagmus Lesions of other portions of the vestibular nuclei did not produce these find

ings This is experimental verification that the clinical syndrome of vestibular neuronitis is reproduced by lesions which affect the vestibular nerve or nerve root. The data indicate the importance of slow phase velocity in diagnosis of lesions of the peripheral and central vestibular system. By comparing effects of lesions on duration and slow phase velocity of induced caloric nystagmus it may be possible to differentiate lesions affecting the vestibular nerve from those which affect the labyrinth

(9) Spontaneous nystagmus after SVN lesions lay in the plane of the ipsilateral anterior canal. The spontaneous nystagmus after SVN destruction was just opposite in direction to that induced by electrical stimulation of SVN before lesion. Considering that all known projections from SVN are inhibitory the directions of the induced eye movements and spontaneous nystagmus agree with the known anatomic connections from SVN to the eye muscle motor nuclei. It is concluded that eye movements in planes parallel to that of the ipsilateral anterior canal are represented in SVN

(10) After lesions of SVN and rostral MVN characteristic changes in caloric nystagmus were noted. These consisted of an enhancement of vertical components of nystagmus induced by stimulation of the contralateral ear with hot or cold water From the directions of the induced nystagmus it was inferred that the enhanced vertical components were due to anterior canal activation Perverted nystagmus after MVN lesions was similar to that after SVN lesions with the exception that perverted nystagmus was also induced by stimulation of the ipsilateral ear with hot water It is postulated that the SVN or MVN lesions caused perverted nystagmus by interrupting commissural pathways which inhibit activity arising in the anterior canals i.e. the lesions caused dysinhibition of anterior canal responses

(11) OKN was not strongly affected by vestibular nuclei lesions but high velocity slow phases of OKN were impaired by labyrinthectomy Directional preponderance of OKN was present after vestibular nuclei lesions It was an accompaniment of spontaneous nystagmus and was equal to or less severe than the directional preponderance of caloric nystagmus OKAN which is prominent in the monkey was reduced to both sides after unilateral labyrinthectomy ipsilateral more than contralateral OKAN was abolished by bilateral labyrinthectomy The vestibular apparatus appears to be an essential structure for maintenance of OKAN

(12) Lesions of the dorsal medullary reticular formation caused head tilt and spontaneous nystagmus in the same direction. In contrast after vestibular nuclei lesions the head tilt and quick phases of spontaneous nystagmus were oppositely directed. Strong directional preponderance of OKN was present in animals with lesions in the dorsal medullary reticular formation and OKAN was lost. Directional preponderance of caloric nystagmus was less strong than that of OKN It is inferred that this portion of the reticular formation has oculomotor as well as body postural functions

11 Conclusions

(1) Changes in body posture and in vestibulo ocular reflexes were studied in monkeys after lesions of the vestibular nuclei and the peripheral vestibular apparatus Based on oculomotor and postural changes after vestibular nuclei lesions the vestibular nuclei were subdivided into separate areas These included ventral LVN dorsal LVN rostral DVN caudal DVN SVN rostral MVN and central caudal MVN

(2) Head tilt and falling tendency were to the ipsilateral side after lesions of lateral or caudal parts of the vestibular nuclei or after lesions of the labyrinth They were to the contralateral side after SVN or rostral MVN lesions Postural changes after central MVN lesions were slight The strongest postural effects were produced by lesions of caudal DVN

(3) Quick phases of nystagmus were not primarily affected by vestibular nuclear lesions All changes in eye movements were conjugate and disconjugate defects similar to those observed after MLF lesions were not produced by unilateral vestibular nuclei destruction

(4) Spontaneous nystagmus was commonly found after vestibular nuclei lesions It was of short duration in light but could persist in darkness for much longer periods of time The direction of the slow phases of spontaneous nystagmus agreed with the direction of the postural change in each of the animals Reversal of spontaneous nystagmus during the recovery course was also noted

(5) Direction fixed positional nystagmus was produced by labyrinthectomy and by lesions of the root entry zone and rostral DVN Positional effects on spontaneous nystagmus were lost after rostral DVN lesion and contralateral labyrinthectomy This finding is in accord with anatomic studies which indicate that rostral DVN is a primary receiving area for activity arising in the otolith organs

(6) Horizontal geotropic direction-changing positional alcohol nystagmus (PAN) was induced to both sides after unilateral labyrinthectomy PAN was lost after bilateral labyrinthectomy or after destruction of rostral DVN and the contralateral labyrinth The rostral DVN lesion had the same effect on positional nystagmus as on PAN This suggests that activity responsible for PAN arises mainly in the otolith organs not in the lateral semicircular canals and is mediated through rostral DVN

(7) Apogeotropic direction-changing positional nystagmus of the type commonly associated with central vestibular lesions cerebellar lesions or the second phase of positional alcohol nystagmus (PAN II) was found after caudal DVN lesion Rotatory direction-changing positional nystagmus was produced by SVN lesions Both caudal DVN and SVN have prominent vestibulo-cerebellar or cerebello-vestibular projections and positional nystagmus is produced by lesions of portions of the cerebellum where these projections originate or end The data support the hypothesis that the cerebellum plays an important role in controlling or mediating utriculo-ocular or sacculo-ocular reflex arcs

(8) Canal paresis i e a reduction in the response of the ipsilateral ear to cold or hot caloric stimulation and a loss of recruitment was found when the root entry zone was damaged After root entry zone lesions there was little effect on the duration of induced nystagmus Lesions of other portions of the vestibular nuclei did not produce these find

EPISTAXIS

A clinical study with special reference to fibrinolysis

By

Bjorn Petruson

GÖTEBORG 1974

CONTENTS

INTRODUCTION

In the antique medicine as well as in most primitive cultures bleeding from the nose has been concepted with great curiosity. To-day we look upon epistaxis in a less mysterious way but still it is an uncomfortable experience upsetting and frightening the patient.

About 60 per cent of the subjects in a western population have suffered from nose bleedings at least once during life. Patients with bleeding from the nose are frequently observed in the daily work at the office as well as in the emergency clinic.

Significant for the symptom nose bleeding is great variation. A few drops of blood once in life might be described by one individual repeated large spontaneous bleedings of long duration by another.

The cause and cource of epistaxis are probably multifactoral. Some etiological factors might explain the start of the nose bleeding, other factors the long duration and the recurrency of the bleeding. Still other factors might predispose to epistaxis. It must however be realized that a factor might predispose to epistaxis at the same time as it might explain a long duration and recurrency of bleeding.

The present investigation comprises a series of clinical and experimental studies centrated around the following questions

Why does the nose bleeding start?

What are the predisposing factors?

What is the mechanism influencing the duration of the bleeding and why are some nose bleedings recurrent?

that 59 per cent of the out patients had had episodes of epistaxis for more than one year. In 22 per cent the actual bleeding was the first bleeding in life.

In hospitalized patients Derbeneva (1970) noted that 7 per cent of the patients suffered from recurrent epistaxis and that 31 per cent bled for the first time in life.

Seasonal variations. In most studies more patients with epistaxis were treated during winter than summer months (Hara 1962, Pierce and Chasin 1962, Serafini 1965, Popiel 1969).

B. Etiology of epistaxis

Upper respiratory infections. The frequency of upper respiratory infections before the epistaxis started has been investigated in several studies (table 1). The great variation of frequency in these studies – between one and a hundred per cent – depends most likely on the principle of selection of the patients and the use of different definitions of upper respiratory infection.

Acetylsalicylic acid. Tucker (1963) is the only author who has reported about the correlation between intake of acetylsalicylic acid and epistaxis. He noted that 4 per cent of the patients had taken acetylsalicylic acid before the bleeding started but regarded this to be coincidental.

In contrast to this, Parry and Wood (1967) discovered that 33 per cent of a control group (patients who visited a hospital due to other diseases than gastro-intestinal haemorrhage) had taken acetylsalicylic acid the week prior to the visit to the hospital.

Hypertension. The association between hypertension and epistaxis was investigated in different studies (Woodruff 1949, Hallberg 195 , Hara 196., Pierce and Chasin 1962, Tucker 1963, Grabowski 1965, Serafini 1965, Phillip and von Harder 1966, Popiel 1969). It is difficult to draw conclusions from the result of these studies as neither control groups are studied nor definitions of hypertension are given.

I two studies (Mitchell 1959 and Shaheen 1970) the blood pressure in the patients with epistaxis was compared with the blood pressure of subjects in control groups. Mitchell found that the diastolic blood pressure was significantly higher in patients who had epistaxis (with no other nasal disease) than in the control group. The blood pressure was, however, not recorded in ?5 per cent of the patients. In contrast to this Shaheen did not find any difference in blood pressure between his patients and a control group.

In the Health Examination Survey of adults 1960–62 (USA), the blood pressure was measured in 6 67 subjects. When the prevalence of different blood pressures was compared with the occurence of epistaxis no correlation was found between subjects with low and high blood pressure and histories of epistaxis (Weiss 197?).

Hematological diseases. In textbooks of hematology (for instance Videbaek 1965) it is said that diseases with defects in the hemostasis and malignant hematopoetic tumours often have epistaxis as a leading symptom.

When patients with epistaxis have been examined, malignant hematopoetic tumours have been reported in one to four per cent and defects in the hemostasis in one to a hundred per cent of the examined patients (table 3). In those studies where the patients were extensively examined with several tests (Laeber and Heinrich 1960, Maurer and Ruhl 1965) more defects in the hemostasis were found.

C. Localisation of the bleeding source

Although the age of the patient is of importance for the localisation of the bleeding source, many results are presented without regard to the age distribution of the patients.

In only one study on 136 hospitalized patients (Ogura and Senturia 1949), was the age distribution presented. All patients less than 15 years old had bleedings from the anterior part of the septum and 60 per cent of the patients more than 40 years of age had bleedings from posterior and lateral parts of the nasal cavity.

Hallberg (195) studied hospitalized patients with severe epistaxis. In ?7 per cent of the patients the bleeding source was localized in the Kiesselbach area and in 17 per cent in other parts of the septum. The bleeding source was seen in other visible parts of the nasal cavity in 33 per cent and was invisible in 23 per cent of the patients.

In out patients examined by Tucker (1963) 74 per cent of the patients had bleedings from septum, 10 per cent bled from other visible parts of the nose and in 16 per cent of the patients the bleeding source was not visible.

CHAPTLR I

REVIEW OF THE LITERATURE

Several studies have been published about etiological factors of epistaxis In the first part of this review the results of etiological analyses from some of the most important clinical studies are presented The results are chosen to serve as references to the present investigation

In the second part different treatments of epistaxis are analysed A third part contains a short review of the vascular anatomy of the nasal mucosa. Finally a short review of the physiology of hemostasis is presented

A Incidence of epistaxis

The incidence of epistaxis in a population sample (U S A) has been studied by Weiss (1972) who found that 7 to 14 per cent of the subject had had epistaxis at least once

A higher frequency of epistaxis in men than in women was noted by Hara (1962) and Tucker (1963) In contrast to this Grabowski (1965) and Popiel (1969) *found the same frequency in men as* in women

In out patients Tucker (1963) reported that 1? per cent of the patients were more than 60 years old and 43 per cent less than ?0 years old In hospitalized patients Hallberg (1952) Hara (196?) and Popiel (1969) noted that 40 respectively 35 and 26 per cent of the patients were more than 60 years old

It is difficult to draw any conclusions about the sex and age distribution of patients treated for epistaxis as the distribution in the population is unknown

Recurrent bleedings. Tucker (1963) reported

Table 1 The frequency of upper respiratory infections (URI) defects in the hemostasis (def hem) and malignant hematopoetic tumours (mal. hem) observed in some clinical studies of epistaxis. The studies were on out p tients (0) or on hospitalized patients (H)

Author		Number of patient in the study	with URI (%)	with def hem (%)	with mal. hem (%)
Newert et al 1948	O	104	1 (1 %)	60 (59 %)	1 (1 %)
Boenninghau 1959	O	147		?	
Laeber and Heinrich 1960	O	40	?	30 (75 %)	
Tucker 1963	O	164	(21 %)	0	0
Maurer and R hl 1965	O	31	31 (100 %)	31 (100 %)	
Phillip and von Harder 1966	O	336	77 (24 %)		
Timm 1966	O	284	(33 %)	?	
Hallberg 1952	H	212	9 (4 %)	2 (10 %)	
Hara 1962	H	1 404	84 (6 %)	118 (8 %)	54 (4 %)
Pierce and Chasin 196	H	13	?		5 (4 %)
Grabowski 1965	H	102	2 (21 %)	1 (1 %)	1 (1 %)
Grunwald 1966	H	34	13 (26 %)	?	
Saraya and Kacker 1966	H	24		5 (21 %)	
Popiel 1969	H	22	(25 %)		4 (2 %)
Derbeneva 1969	H	640	10 (2%)		
Serafini 1965	?	606	87 (14 %)	10 (2 %)	

increase during influenz epidemic

that 59 per cent of the out patients had had episodes of epistaxis for more than one year. In 22 per cent the actual bleeding was the first bleeding in life.

In hospitalized patients Derbeneva (1970) noted that 7 per cent of the patients suffered from recurrent epistaxis and that 31 per cent bled for the first time in life.

Seasonal variations. In most studies more patients with epistaxis were treated during winter than summer months (Hara 1962, Pierce and Chasin 1962, Serafini 1965, Popel 1969).

B. Etiology of epistaxis

Upper respiratory infections. The frequency of upper respiratory infections before the epistaxis started has been investigated in several studies (table 1). The great variation of frequency in these studies – between one and a hundred per cent – depends most likely on the principle of selection of the patients and the use of different definitions of upper respiratory infection.

Acetylsalicylic acid. Tucker (1963) is the only author who has reported about the correlation between intake of acetylsalicylic acid and epistaxis. He noted that 4 per cent of the patients had taken acetylsalicylic acid before the bleeding started but regarded this to be coincidental.

In contrast to this, Parry and Wood (1967) discovered that 33 per cent of a control group (patients who visited a hospital due to other diseases than gastro-intestinal haemorrhage) had taken acetylsalicylic acid the week prior to the visit to the hospital.

Hypertension. The association between hypertension and epistaxis was investigated in different studies (Woodruff 1949, Hallberg 195 , Hara 196 , Pierce and Chasin 1962, Tucker 1963, Grabowski 1965, Serafini 1965, Philip and von Harder 1966, Popel 1969). It is difficult to draw conclusions from the results of these studies as neither control groups are studied nor definitions of hypertension are given.

In two studies (Mitchell 1959 and Shaheen 1970) the blood pressure in the patients with epistaxis was compared with the blood pressure of subjects in control groups. Mitchell found that the diastolic blood pressure was significantly higher in patients who had epistaxis (with no other nasal disease) than in the control group. The blood pressure was, however, not recorded in .5 per cent of the patients. In contrast to this Shaheen did not find any difference in blood pressure between his patients and a control group.

In the Health Examination Survey of adults 1960–62 (USA), the blood pressure was measured in 6 672 subjects. When the prevalence of different blood pressures was compared with the occurence of epistaxis no correlation was found between subjects with low and high blood pressure and histories of epistaxis (Weiss 1972).

Hematological diseases. In textbooks of hematology (for instance Videbæk 1965) it is said that diseases with defects in the hemostasis and malignant hematopoetic tumours often have epistaxis as a leading symptom.

When patients with epistaxis have been examined, malignant hematopoetic tumours have been reported in one to four per cent and defects in the hemostasis in one to a hundred per cent of the examined patients (table 1). In those studies where the patients were extensively examined with several tests (Laeber and Heinrich 1960, Maurer and Riehl 1965) more defects in the hemostasis were found.

C. Localization of the bleeding source

Although the age of the patient is of importance for the localization of the bleeding source, many results are presented without regard to the age distribution of the patients.

In only one study on 136 hospitalized patients (Ogura and Senturia 1949) was the age distribution presented. All patients less than 15 years old had bleedings from the anterior part of the septum and 60 per cent of the patients more than 40 years of age had bleedings from posterior and lateral parts of the nasal cavity.

Hallberg (195) studied hospitalized patients with severe epistaxis. In 27 per cent of the patients the bleeding source was localized in the Kiesselbach area and in 17 per cent in other parts of the septum. The bleeding source was seen in other visible parts of the nasal cavity in 33 per cent and was invisible in 23 per cent of the patients.

In out-patients examined by Tucker (1963) 74 per cent of the patients had bleedings from septum, 10 per cent bled from other visible parts of the nose and in 16 per cent of the patients the bleeding source was not visible.

D Treatment of epistaxis

In ancient times epistaxis was treated in several different ways for example with gauze tampons and cauterisation In ancient Egypt both nasal cavities were completely filled with gauze when the patients had epistaxis (Kassel 1911) By local pressure to a visible or unvisible vessel the bleeding was arrested Various cauterizing agents were used *in ancient Greece and Rome* for example acetum, gallotanic acid antimony and soda (Kassel 1913) The drugs were in different ways introduced into the bleeding nasal cavity and part of the nasal mucosa was in this way destroyed Modifications of both these methods have been in use since then

1 Local treatment

a *Bleeding vessel or area visible.* Nowadays cauterisation is performed with chemicals like silver nitrate trichlor acetic acid or chromic acid or with electrical cauterization (Woodruff 1949 Ogura and Senturia 1949 Hallberg 1952 Hara 1962 Tucker 1963 Stecker and Lake 1965 Call 1969) and only the bleeding area or vessel is destroyed

A refined method of cauterization was described by Ringenberg (1963) With the aid of an operating microscope the bleeding vessel was identified the blood from the vessel was eliminated by suction and *the vessel destroyed by electrical* cauterization

Submucosal injections below the bleeding area have been performed with 3% water soluble Phlebocid® (Wodak 1966) The submucosal injection helped to arrest the bleeding by local pressure and Phlebocid gave an inflammatory reaction in *the mucosa with thrombophlebitis in the vessels.*

Submucosal injections with adrenalin 1 1 000 which give a vasoconstriction have been used by Kocsard Varo (1967) Adrenalin and other vasoconstrictor drugs are used for routine purpose on the mucosa surface

Frable (1968) sprayed a thin layer of plastic over the bleeding area *The bleeding was arrested* by local pressure without damage of the mucosa

The absorbable hemostatic sponge Spongostan® (Mayer 1952) and Surgicel® (Tibbels 1963) can be used when the bleeding is profuse Spongostan® and Surgicel® are preformed networks in which blood clotting is facilitated

Patients with recurrent epistaxis due to large visible vessels on the nasal septum were treated by *cutting the vessel to the cartilage* at various sites (Pinsker and Holdcraft 1971) This treatment gave several scars in the nasal mucosa The scars were said to prevent new bleedings

Defects in the vessels of the nasal mucosa can be treated with skin transplants (Saunders 1964) *Parts of the nasal mucosa are replaced with skin* The treatment is used in patients with hereditary hemorrhagic telangiectasia (Mb Osler) and septal perforations.

b *Bleeding vessel or area invisible* Usually anterior or posterior tampons of gauze or cotton have been used to treat invisible bleedings. Stevens (1951) and Bavon (1965) used a rectangular shaped balloon filled with water instead of an anterior gauze tampon The filled balloon arrested the bleeding by local pressure

A Foley balloon catheter was used instead of post nasal packing with tampons by Rege et al (1964) Fenn (1968) Brunnel (1968) and Barton and Ray (1970) *The inflated balloon* which filled up the entire epipharyngeal space prevented posterior bleedings by local pressure

Intranasal freezing with a Steven s balloon have been performed by Bluestone and Nixon (1970) and Hill and Jaccewics (1971) After freezing at -20^{0}C for one hour a severe inflammatory reaction *was observed in the nasal mucosa* with thrombophlebitis in the vessels. Many medium sized vessels were permanently damaged

A severe inflammatory reaction in the nasal mucosa with thrombophlebitis in nasal vessels can also be produced by treatment with radiotherapy (Stewart and Sammon 1954 Salomon and Buch *Rasmussen 1965 Lord and Durden Smith 1971)* In the investigations mentioned 1 500 to 3 000 r were given on both nasal cavities.

An injection of 2 per cent Lidocain® into fossa pterygopalatinae has been described as successful in severe posterior bleedings (Padmos 1968) Lidocain® gave a vasoconstriction of the spheno *palatine artery* and was reported to arrest the bleeding in 10 cases out of 11

As a rule arterial ligation of the external carotid artery or its branches or of the anterior ethmoidal artery has been successful when other local treatments have failed (Weddel et al 1945 MacBeth 1948 Hunter and Gibson 1969 Shaheen 1970)

The blood flow to the bleeding area decreased after the ligation and the bleeding was arrested in most cases

2. General treatment

It is a well known clinical observation that epistaxis sometimes is arrested when the patient is treated with tranquilizing drugs. Hypnosis was valuable in one case with recurrent nose bleedings (MacCord 1968).

Defiency of vitamin C and K might give defects in the hemostasis. These vitamins were used in the therapy of epistaxis by Nevert et al (1948) and Kocard-Varo (1967)

A patient who has a hematological disease with generalized defects in the hemostasis must be treated with drugs or transfusions in a suitable way (Morel and Belleville 1967)

Oestrogen hormones are described as suitable therapy in patients with repeated epistaxis as for example patients with Mb Osler (Jacobsen 1964 Harrison 1964). In what way the nose bleedings are arrested and prevented is not sufficiently investigated

Antifibrinolytic drugs have been used in patients with repeated epistaxis. As rule only single cases have been reported but in these patients the effect of the drugs is described as good. The drugs available are

Epsilon-amino-caproic acid EACA (Mikata et al 1959 Buch-Rasmussen 1966)

Para amino-methyl-benzoic acid PAMBA (Hoffman and May 1967 Nuenbergk 1967)

Tranexamic acid AMCA (Marx and Mesmer 1968)

Topical application of EACA effectively arrested epistaxis in patients with hereditary hemorrhagic telangiectasia (Mb Osler) (Kwaan and Silverman 1973)

In a study on 50 patients with epistaxis Jash (1973) sprayed 10 ml EACA thoroughly in the nasal cavity and noted relief from nasal bleeding in 83 per cent of the patients

Spongostan soaked with tranexamic acid was found to be suitable as therapy in patients with profuse bleedings (Petruson 1971)

Up to now double blind study with antifibrinolytic drugs has been reported

E. Vascular anatomy of the nasal mucosa — a short review

The first detailed study of the blood supply of the nasal cavity was performed by Zuckerkandle (1885). Since that time a large number of investigations have been reported on this subject. Mostly injection preparations have been performed either on animals (Swindle 1935) or on man (Burnham 193 Shaheen 1970). Batson (1954) used corrosion technique according to Spalteholz. Naumann (1961) published a detailed study of the microvascular architecture and function in the nasal mucosa.

According to these studies we now have rather good knowledge about the vascular architecture in the nasal cavity

Arteries. The *internal carotid artery* furnishes through the ophtalmic artery the anterior and posterior ethmoidal arteries (figure 1 and)

In man the anterior ethmoidal artery normally is much the larger and supplies the anterior third of the lateral wall of the nasal cavity and a similar portion of the septum.

The posterior ethmoidal artery is limited in its distribution to the region of the superior concha and the corresponding portion of the septum

From the *external carotid artery* are derived the sphenopalatine artery as well as the greater palatine artery (in the internal maxillary artery). The superior labial branch of the facial artery is derived from the external maxillary artery

The sphenopalatine artery supplies the posterior and lower parts of the lateral wall and the septum. It has three branches which take a course partly in bony canals, partly in the periosteal layer of the nasal mucoperiosteum (Burnham 1935)

Proximal branches of the greater palatine artery furnish the lower posterior portion of the nasal fossa. Distal branches from the same artery supply a portion of the floor of the anterior part of the nasal fossa. The superior labial branch of the facial artery is distributed to the anterior part of the septum.

All arteries communicate frequently with one another. On the anterior portion of the septal cartilage the anastomoses are situated superficially in the mucosa. This site is known as Kiesselbach's area

According to Shaheen (1970) the ethmoidal

Up to now no double blind study with antifibrinolytic drugs has been reported

E. Vascular anatomy of the nasal mucosa – a short review

The first detailed study of the blood supply of the nasal cavity was performed by Zuckerkandle (1885). Since that time a large number of investigations have been reported on this subject. Mostly injection preparations have been performed either on animals (Swindle 1935) or on man (Burnham 1935, Shaheen 1970). Batson (1954) used corrosion technique according to Spalteholz. Naumann (1961) published a detailed study of the microvascular architecture and function in the nasal mucosa.

According to these studies we now have rather good knowledge about the vascular architecture in the nasal cavity

Arteries. The *internal carotid artery* furnishes through the ophtalmic artery the anterior and posterior ethmoidal arteries (figure 1 and 2)

In man the anterior ethmoidal artery normally is much the larger and supplies the anterior third of the lateral wall of the nasal cavity and a similar portion of the septum.

The posterior ethmoidal artery is limited in its distribution to the region of the superior concha and the corresponding portion of the septum.

From the *external carotid artery* are derived the sphenopalatine artery as well as the greater palatine artery (via the internal maxillary artery). The superior labial branch of the facial artery is derived from the external maxillary artery

The sphenopalatine artery supplies the posterior and lower parts of the lateral wall and the septum. It has three branches which take a course partly in bony canals, partly in the periosteal layer of the nasal mucoperiosteum (Burnham 1935).

Proximal branches of the greater palatine artery furnish the lower posterior portion of the nasal fossa. Distal branches from the same artery supply a portion of the floor of the anterior part of the nasal fossa. The superior labial branch of the facial artery is distributed to the anterior part of the septum.

All arteries communicate frequently with one another. On the anterior portion of the septal cartilage the anastomoses are situated superficially in the mucosa. This site is known as Kiesselbach's area.

According to Shaheen (1970) the ethmoidal

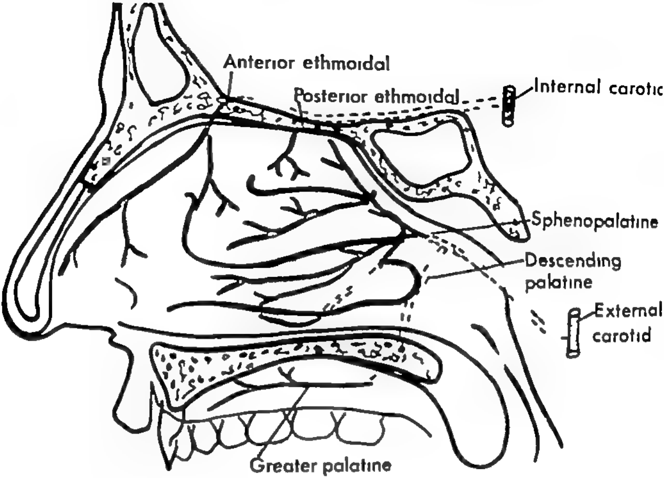

Figure 1 Arteries of the lateral nasal wall

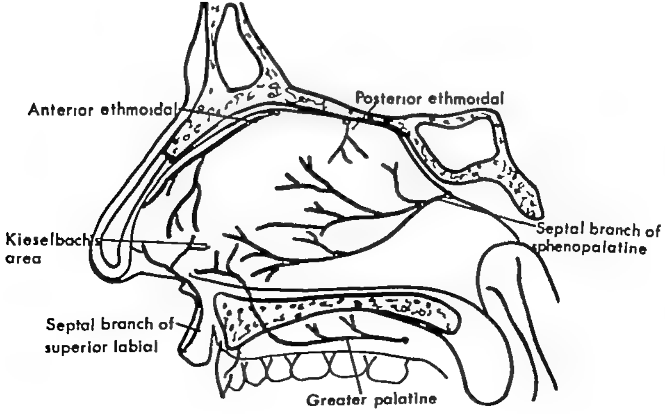

Figure .. Arteries of the nasal septum.

arteries contribute very little to the arterial vasculature of the nose. On the basis of intravital dye studies he also showed that the intranasal anastomoses, which link the two main arterial systems, are capable of accommodating a rapid and substantial migration of blood. This is what happens when the pressure in one of the systems is lowered after for instance ligation of the external or internal carotid artery or their branches.

Veins. The venous blood from the nasal mucosa passes to the external nasal plexus, the nasolacrimal plexus, anterior and posterior ethmoidal veins, veins behind and above the palate veins in the lateral part of the epipharynx, the sphenopalatine vein and the sphenoidal venous plexus.

Microvascular architecture. Our knowledge of the microvascular architecture in different parts of the nasal mucosa is based mainly on works by Burnham (1935) Swindle (1935) Messerklinger (1958) and Naumann (1961). A sketch with the proposed function of the minute vessels of the nasal mucosa based on other studies has been presented by Ingelstedt and Rundkrantz (1964) (figure 3)

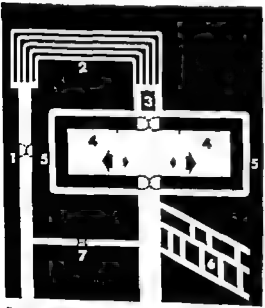

Figure 3 Sketch of the minute vessels of the nasal mucosa. 1 Arteriole. 2 Capillary network. 3 and 5 Postcapillary venules. 4 Sinusoid range of possible expansion of filled sinusoid. 6 Deep venous plexus. 7 Arteriovenous anastomosis. (Ingelstedt & Rundcrantz 1964)

The small arteries either communicate with small veins through arterio-venous anastomoses or with capillary networks. Three different capillary networks are described one in the periosteal layer another supplies the glands in the mucosa and the third in the subepithelial layer These networks are connected with one another and may empty either in venous plexuses or in sinusoidal spaces in the erectile tissue draining to deep intraosseous plexuses of veins. The venous plexuses give place to veins which increase in size but decrease in number and accompany the arteries.

The venous pathways in the turbinate areas differ from those in other parts of the nasal mucosa. In the mucosa of the inferior and middle turbinate and in some parts of the septum sinusoidal spaces with frequent intercommunications are situated. In the walls of these sinusoides are sphincters with ability to vary the calibre of the space within wide limits.

Innervation. The vessels of the nasal mucosa are innervated through autonomic sympathetic fibers which are vasoconstrictors and autonomic parasympathetic fibers which are vasodilatators (Larsell and Fenton 1936 Messerklinger 1958).

The vasomotor reactions of the vascular bed are also affected by vasoactive drugs for example adrenalin and acetylcholin (Naumann 1961).

Vascular bed reactions. The vascular bed in general reacts in a similar way on different traumatic agents (Brånemark 1968). The first sign of damage to the vascular bed is a slow circulation of blood corpuscles first seen in small veins This is followed by adhesion to the vessel wall of erythrocytes, platelets and leucocytes. Later on there is stasis in the vessels and development of microthrombi consisting of a fibrin network and blood corpuscles. The microthrombi might be washed away or they may completely block the vessels causing damage to the surrounding tissue

Naumann (1961) has shown that the vascular bed in the nasal mucosa reacts in the same way as described. From intravital microscopic observations on the nasal membranes of rabbits he has noted that mechanical stimulation gave a constriction of capillaries and veins with slow corpuscular circulation and sometimes stasis and white emboli. The arteries were usually only slightly constricted.

In man Naumann had the clinical experience that small mechanical stimulations only slightly

CHAPTER 2

CLINICAL MATERIAL

Study groups

In this investigation subjects in a randomly selected population sample and patients who visited an ENT doctor due to epistaxis were studied. The subjects and patients were both asked questions in a questionnaire (chapter 3 A).

A. Population sample (P)

By the aid of a computer 439 inhabitants in the city of Goteborg were selected at random from the census register containing 450 000 subjects. In the ages under 60 years about every thirteen hundredth man and woman was selected. The selected subjects were divided into six groups with regard to sex and age. In the ages over 60 years about every seven hundredth man and woman was selected and divided into two groups with regard to sex. The reason why more subjects over 60 years of age were selected was a desire to get about an equal number of subjects in each group (table 2).

To selected subjects a questionnaire (chapter 3 A) was sent one of the four weeks 48, 49, 50 (1971) or 4 (1972).[1] Those who did not return the questionnaires which were sent out the first three weeks were questioned by telephone the fourth week.

Answers were received from 410 subjects (93 %). Of those who answered 9 per cent were questioned by telephone. In all questionnaires all questions were answered. Those who did not answer were equally distributed in the groups (table 2).

B. Registered patients (R)

Before this study started questionnaires (chapter 3 A) were sent to all ENT-doctors (about 40) in the city of Goteborg. The doctors were told to ask some questions to all patients with epistaxis who visited the different practices or the hospital during the period from 1 July 1970 to 31 December 1971. The medical assistants were told to hand over a questionnaire to the doctor every time a

[1] Within these dates the questionnaires were distributed at random.

and reversibly affected the vascular bed He assumed however that the same stimulation in an inflammatory nasal mucosa gave a more severe vascular bed reaction

When an inflammatory reaction was induced in the nasal mucosa of rabbit (Naumann 1961) for example by application of a drop of mustard oil a miximal vasodilatation and rapid blood flow was primary observed in all vessels After about 30 minutes no dilatation was seen and the blood flow was normal again Later on slowly moving leucocytes were noted along the vessel walls leucocyte diapedesis was also observed When the induced reaction was severe white emboli fibrin networks and finally fibrin-platelet plugs were formed in the vessels There was also noted increasing injuries in the vessel walls.

F Physiology of hemostasis – a short review

The physiology of hemostasis has been extensively studied during the last century During this period numerous investigations have also been published about different defects in the hemostasis In this short review is presented some basic facts available in text books of hemostasis (Nilsson 1971 Biggs 1972)

Hemostasis includes all mechanisms involved in arresting the bleeding. It is composed of four components vessel wall reaction platelet aggregation coagulation and fibrinolysis (figure 4)

Vessel wall reaction ⟶ vasoconstriction
Platelet aggregation ⟶ platelet plug formation
Coagulation ⟶ fibrin clot
Fibrinolysis ⟶ break down of fibrin

Figure 4 Schema of the hemostasis

Vessel wall reaction. When a vessel is damaged a vasoconstriction of short duration is initiated by a neurogenic or humoral mechanism. This reaction is of great hemostatic importance after injuries of both arteries and veins. During the vasoconstriktion the formation of a platelet plug starts

Platelet aggregation. When the vessel is injuried the endothelial cells are damaged and the subendothelial collagen denuded Platelets progressively adhere to the collagen The aggregated platelets release factors which aggregate new platelets and finally a platelet plug is formed This is called primary hemostasis.

Coagulation. After a while fibrin threads appear in the platelet plug and form a weak network The fibrin originates from fibrinogen circulating in the blood The fibrinogen is converted to fibrin by the enzyme thrombin which in turn is formed from prothrombin activated by different coagulation factors. The thrombin also aggregates platelets and the platelets in turn release factors that activate prothrombin In this way both the platelet aggregation and the development of fibrin is accelerated Finally a dense network of fibrin platelets and erythrocytes, a blood clot has been formed

Fibrinolysis is an enzymatic break down of the fibrin network in the clot by means of plasmin The inactive plasminogen circulates in the blood and is incorporated in the clot Different activators for example blood activator tissue activator and the bacterial toxins streptokinase and staphylokinase can activate plasminogen The split products formed when the fibrin is digested act as inhibitors of the platelet aggregation and the polymerisation of fibrin threads. In this way this stage of the hemostatic processes come to a steady state

CHAPTER 2

e
to
ho

patient with epistaxis was examined During the period 1 118 patients with epistaxis were registered, 88 per cent were registered at the hospital and 12 per cent at different practices outside the hospital

Most of the patients came directly to the hospital even if the way was shorter to an ENT-doctor outside the hospital In the afternoons and nights and on week-ends and holidays all patients with epistaxis had to visit the hospital because all practices outside the hospital were closed

The number of patients who were registered during different months is shown in figure 5 The number of patients in different sex and age groups is presented in table 2

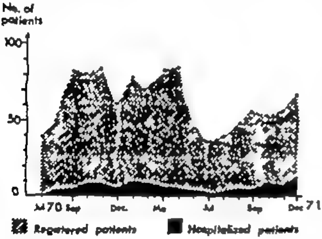

Figure 5. The number of patients who were registered and hospitalized during different months.

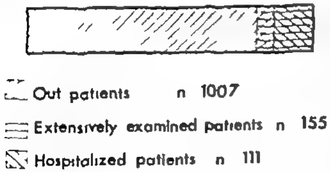

Figure 6. The different study groups of the registered patients.

The group of registered patients is composed of out patients and hospitalized patients (figure 6) *Hospitalized patients (H)* During the registration period 111 of the registered patients were hospitalized due to epistaxis They were divided into eight groups with regard to sex and age (table 2)

Out patients (O). The 1 0007 out patients were divided into different sex and age groups (table 2)

Extensively examined patients (E) This group of patients constitutes the 111 hospitalized patient and 44 out patients selected at random from patients who came to the out patient department of the hospital between 9 and 12 a.m any of the days Monday to Thusday Age and sex distribution of these 155 patients is presented in table 2.

Blood pressure was recorded and samples from the nose and throat for bacterial isolation were taken in the patients when they were examined for the first time

Blood samplings for routine tests (chapter 3 F) serological tests (chapter 3 G) and routine tests of hemostasis (chapter 3 H) were performed at different lenghts of time after the first examination The samplings were carried out immediately the patients came to the hospital in 74 patients within 24 hours after the hospitalisation in 49 patients and after more than 24 hours hospitalisation in 37 patients.

During hospitalisation blood pressure hemoglobin concentration and reticulocyte counting were carried out repeatedly In out patients these tests were performed a second time two to four days after the first examination.

All patients were finally examined 17±10 days (range 8–42 days) after the first blood samplings were taken. On this occasion the blood pressure was recorded samples from the nose and throat taken for bacterial isolation blood samplings taken for determination of hemoglobin concentration erythrocyte sedimentation rate leucocyte count reticulocyte count serological tests and the routine tests of hemostasis fibrinogen APTT blood clotting factor VIII and II + VII + X The tests of capillary fragility bleeding time and platelet count were only performed in those patients who had an abnormal value on the first test occasion.

Subgroups. Some of the extensively examined patients who came to the hospital during the autumn 1971 were at random selected for the investigations of fibrinolytic activities of blood and nasal mucosa (chapter 4 I and 4 K) and histological examination of the nasal mucosa (chapter 4 D) These patients are presented individually in the separate chapters.

CHAPTER 3

METHODS

A. The questionnaires

The subjects in the population sample (P), the out patients (O), the hospitalized patients (H) and the extensively examined patients (E) were asked the following questions.

1. Has any doctor at any time found that you have had high blood pressure? yes – no (POH)
2. Do you regularly take drugs as treatment for high blood pressure? yes – no (PH)
3. Have you at any time during the last seven days taken any drugs as treatment for headache, aches, or pains? (the names of eight of the most common drugs containing acetylsalicylic acid were mentioned) yes – no (POH)
4. Have you at any time during the last seven days had a common cold, caught, sore throat or fever? yes – no (POH)
5. Have you any time consulted a doctor and been treated for nose bleeding? yes no (P)
6. Have you had any nose bleeding the last seven days? (yes – no (P)
7. How often do you bleed from the nose
   a. Never had any bleeding (P)
   b. First time in life (OH)
   c. Have had single bleedings before (POH)
   d. Have had single bleedings every year (POH)
   e. Have had several bleedings every year (POH)
8. Do you use to bleed from the nose when you have a common cold? yes – no (P)
9. Do you use to bleed from the nose when you are tired and/or busy and/or stressed? yes – no (P)
10. Did the bleeding start (OH)
    a. When you blew your nose?
    b. When you sneezed?
    After picking the nose?
    d. After a blow against the nose?
    e. After puncture of sinus owing to sinusitis?
    f. After physical exhaustion?
    g. After psychical exhaustion?
    h. Without any obvious reason?
11. Do you have any near relatives who use to bleed from the nose frequently? Parents yes – no Children yes – no Brothers or sisters yes – no (E)
12. Do you use to get hematomas on the arms (yes – no) or on the body (yes – no) without traumas? (E)
13. Do you use to bleed for a long time after a tooth extraction (yes – no) or after slight skin cuts (yes – no)? (E)

B. Clinical examination

After the clinical examination of the patients the examinating doctor classified the localisation of the bleeding source and the kind of bleeding. The bleeding might come from 1. Kiesselbach area 2. Other visible parts of the septum 3. Visible lateral parts and floor of the nose 4. Invisible localisation.

When the kind of bleeding was noted the following five groups were used 1. Distinct arterial bleeding 2. Distinct venous bleeding 3. Profuse bleeding 4. Kind of bleeding impossible to classify 5. No bleeding when examined.

C. Principles of treatment

The principles of treatment were to arrest the bleeding with as little damage to the nasal mucosa as possible.

When the patient called the doctor by telephone, the patient was told to blow the nose to get rid of old blood clots in the nose. He was also

told to sit up breath through the mouth and press the nares together between the thumb and fore finger for 10 minutes.

If the bleeding in spite of this continued the patient was told to blow the nose once again then put up a large piece of cotton soaked with paraffin (if available) in the nose and apply the finger grip for another 10 minutes.

If the nose bleeding continued the patient was instructed to visit the doctor

Before the examination the patient was told to blow this nose remaining clots were evacuated with suction and the bleeding source localized. The main lines of the doctors local treatment were as follow

Visible bleeding source. A piece of cotton soaked with local anesthesia and a vasoconstrictor was put into the bleeding nasal cavity if the bleeding source was *distinct* and visible on the septum. The cotton was taken away after the bleeding was arrested. As small area of the mucosa as possible was then cauterized by touching with solid cromic acid on a small steel wire for a second. The excess of acid was washed away with saline not sodium hydroxide which destroys the surrounding mucosa (Brånemark 1974) Electrical cautery was used in visible severe arterial bleedings.

A visible *profuse* bleeding on the septum or lateral parts or the floor of the nose was treated in a new way with a gelatine sponge (Spongostan®) which has a hemostatic effect soaked with a 10 per cent solution of tranexamic acid (Cyklokapron®) which has an antifibrinolytic effect. The soaked Spongostan® was placed against the bleeding area. Sometimes invisible small bleedings were treated in this way too. Most of the bleedings treated with Spongostan® and Cyklokapron® were bleedings which, before this investigation started, were treated with anterior gauze tampons. The Spongostan® disappeared by itself without any complications within two or three days in forward or backward direction.

Invisible bleeding source. When the bleeding source could be suspected to be localized in anterior and/or superior parts of the nasal cavity the patient was treated with gauze tampons after local anesthesia had been sprayed on the nasal mucosa. The tampons were packed into the nose until they filled up the anterior and/or superior parts of the bleeding nasal cavity and arrested the bleeding by local pressure

In bleedings localized in posterior parts of the nose both a posterior Foley catheter tampon (nr 14) and anterior gauze tampons were used. The tip of the catheter outside the balloon, was first cut. The balloon of the catheter which then was placed in epipharynx and filled with about 10 ml saline, occluded the posterior parts of the nose and prevented the anterior gauze tampons disappearing down the throat. The whole bleeding nasal cavity was packed with anterior gauze tampons. Finally the catheter was fixed forward with a plastic tube clamp. The external naris was protected against pressure injuries by a cut eye pad below the clamp.

All patients who were treated with posterior and anterior tampons were hospitalized as well as some of the patients who were treated with anterior tampons. Schema for removement of the tampons is described in chapter 4 L.

In all patients the therapy was regarded as successful if no new bleeding which required new local treatment occured within 24 hours after the patient had left the examining doctor

D Blood pressure

The blood pressure was measured according to Rose and Blackburn (1968) with a sphygmomanometer attached to a 13 cm wide and 26 5 cm long cuff on the right over arm. The readings were made after 4–5 minutes rest with attached cuff in a sitting position with the right arm placed horisontally on a table The cuff was rapidly inflated to a level above the radial palpatory pressure and then deflated. The systolic pressure was determined when the sound of the brachial artery was heard in the stethoscope (phase I) and the diastolic pressure when no sound was heard (phase V).

All readings, except part of the first ones, were made between 9 and 12 a.m. by the author Of various readings in the same patient the pressure recorded at the final examination, was used in this investigation.

E. Bacterial isolation

The first samples for bacterial isolation were always taken from the nose and throat before the patients were treated. One sample was taken by

the aid of a nose speculum from the posterior parts of the middle meatus on the side opposite to the bleeding. Another sample was taken from the throat.

The second samples were taken in the same way 17±10 days (range 8–42 days) after the first.

All bacterial isolations were performed at the Bacteriological Department of the hospital. All bacterial strains of beta-hemolytic streptococci and staphylococcus aureus which were found were frozen and kept for later determination of the fibrinolytic activity (chapter 3 1).

F. Routine tests

The following tests were performed at the Central Chemical Department of the hospital using standard methods. The ref rence values stated by the Department are presented.

I. Hemoglobin concentration (standardized with hemoglobin-cyanide standard, Merck) reference value
   men 13 2–16 6 g/100 ml
   women 11 6–14 9 g/100 ml
II. Erythrocyte sedimentation rate reference value
   men ≤ 20 mm/hr
   women ≤ 28 mm/hr
III. Leucocyte count (microscopic counting) reference value 3 500–9 000 leucocytes/mikrolliter
IV. Reticulocyte count (microscopic counting) reference value 0.2–1 0 percentage of total erythrocytes
V. Creatinine concent ation in serum
   reference value men 0 7–1 3 mg/100 ml
   women 0.6–1 2 mg/100 ml
VI. Transaminases in serum Aspartate aminotransferase (ASAT or GOT) and alanine aminotransferase (ALAT or GPT) were determined by kinetic technique using commercial reagents (Boehringer Mannheim, catalogue numbers 15957 and 15958) at an incubation temperature of 30°C
   reference alue
   7 U/l
   7 U/l

G. Serological tests

Blood samples for serological tests were analysed at the Bacteriological Department of the hospital. The reference values stated by the Department are presented.

I. Antistreptolysine titer (AST) reference value a difference of two titer steps or more between the two test occasions or a single test value of more than 400 U/ml.
II. Antistaphylolysine titer (ASTA) reference value a difference of two titer steps or more between the two test occasions or a single test value of more than 4 U/ml.
III. C reactive protein (CRP) was determined according to Nilsson (1968) reference value less than 5 μg/ml

H. Routine tests of hemostasis

Tests of vessel and platelet functions and blood clotting were performed at the Coagulation Laboratory of the hospital. The reference values and abnormal values indicating defects in the hemostasis stated by the Laboratory are presented.

I. Capillary fragility Two methods were used, 123 patients were tested with the stasis method and 12 patients with the suction method.

   The stasis method. a 13 cm wide and 26.5 cm long cuff was placed around the left over arm and inflated to 70 mm Hg for 5 minutes. Abnormal value more than 15 petechiae within a circle with 5 cm diameter on the forearm 2 minutes after the cuff was deflated.

   The suction method a suction cup of 1 cm diameter was placed on the back of the shoulder and a negative pressure of 20 mm Hg applied for 1 minute.

   Abnormal alue more than 7 petechiae in the suction area 2 minutes after the cup was taken away
II. Bleeding time. Two methods were used, 126 patients were tested with Dukes method and 12 patients with a modification of Ivys method.

   Abnormal values:
   ≥ 4 minutes with Dukes method
   ≥ 11 minutes with Ivys method

told to sit up, breath through the mouth and press the nares together between the thumb and fore finger for 10 minutes.

If the bleeding in spite of this continued the patient was told to blow the nose once again then put up a large piece of cotton soaked with paraffin (if available) in the nose and apply the finger grip for another 10 minutes.

If the nose bleeding continued the patient was instructed to visit the doctor

Before the examination the patient was told to blow this nose remaining clots were evacuated with suction and the bleeding source localized. The main lines of the doctors local treatment were as follow

Visible bleeding source. A piece of cotton, soaked with local anesthesia and a vasoconstrictor was put into the bleeding nasal cavity if the bleeding source was *distinct* and visible on the septum. The cotton was taken away after the bleeding was arrested. As small area of the mucosa as possible was then cauterized by touching with solid cromic acid on a small steel wire for a second. The excess of acid was washed away with saline not sodium hydroxide which destroys the surrounding mucosa (Brånemark 1974) Electrical cautery was used in visible severe arterial bleedings.

A visible *profuse* bleeding on the septum or lateral parts or the floor of the nose was treated in a new way with a gelatine sponge (Spongostan®) which has a hemostatic effect, soaked with a 10 per cent solution of tranexamic acid (Cyklokapron®) which has an antifibrinolytic effect. The soaked Spongostan® was placed against the bleeding area. Sometimes invisible small bleedings were treated in this way too. Most of the bleedings treated with Spongostan® and Cyklokapron® were bleedings which, before this investigation started, were treated with anterior gauze tampons. The Spongostan® disappeared by itself without any complications within two or three days in forward or backward direction.

Invisible bleeding source. When the bleeding source could be suspected to be localized in anterior and/or superior parts of the nasal cavity the patient was treated with gauze tampons after local anesthesia had been sprayed on the nasal mucosa. The tampons were packed into the nose until they filled up the anterior and/or superior parts of the bleeding nasal cavity and arrested the bleeding by local pressure.

In bleedings localized in posterior parts of the nose both a posterior Foley catheter tampon (nr 14) and anterior gauze tampons were used. The tip of the catheter outside the balloon, was first cut. The balloon of the catheter which then was placed in epipharynx and filled with about 10 ml saline occluded the posterior parts of the nose and prevented the anterior gauze tampons disappearing down the throat. The whole bleeding nasal cavity was packed with anterior gauze tampons. Finally the catheter was fixed forward with a plastic tube clamp The external naris was protected against pressure injuries by a cut eye pad below the clamp.

All patients who were treated with posterior and anterior tampons were hospitalized as well as some of the patients who were treated with anterior tampons. Schema for removement of the tampons is described in chapter 4 L.

In all patients the therapy was regarded as successful if no new bleeding which required new local treatment occured within 24 hours after the patient had left the examining doctor

D Blood pressure

The blood pressure was measured according to Rose and Blackburn (1968) with a sphygmomanometer attached to a 13 cm wide and 26.5 cm long cuff on the right over arm. The readings were made after 4–5 minutes rest with attached cuff in a sitting position with the right arm placed horisontally on a table. The cuff was rapidly inflated to a level above the radial palpatory pressure and then deflated. The systolic pressure was determined when the sound of the brachial artery was heard in the stethoscope (phase I) and the diastolic pressure when no sound was heard (phase V).

All readings, except part of the first ones, were made between 9 and 12 a.m. by the author Of various readings in the same patient the pressure recorded at the final examination, was used in this investigation.

E. Bacterial isolation

The first samples for bacterial isolation were always taken from the nose and throat before the patients were treated. One sample was taken by

+ = fibrinolytic activity demonstrable
++ = fibrinolytic activity less than reference strain H 64
+++ = fibrinolytic activity equal to the reference strain H 64
++++ fibrinolytic activity stronger than the reference strain H 64

K. A method for determination of fibrinolytic activity in euglobulin precipitate from blood plasma

The fibrinolytic activity in blood can be demonstrated by different methods. The most physiological method probably is the whole blood clot lysis time. Unfortunately this method is insensitive and can only be used when there is a markedly increased fibrinolytic activity. At low levels of fibrinolytic activity the lysis time is long and the end point reading difficult.

When low levels of fibrinolytic activity are studied it is more suitable to use the euglobulin precipitation method. The euglobulin fraction from plasma is after dilution precipitated at pH 5 to 6.4. Most of the fibrinolytic activity is found in the precipitate while most of the fibrinolytic inhibitors remain in the supernate (Kowalski et al 1959, Blix 1964, Ygge 1970).

The fibrinolytic activity in the euglobulin precipitate can be measured in two ways, either as euglobulin clot lysis time or by means of the fibrin plate method. When weak fibrinolytic activity is measured the lysis time is very long by the clot lysis time method and variations in fibrinogen concentrations in the euglobulin fraction interfere with the results (Ygge 1970).

The fibrin plate method which was introduced by Permin (1947, 1950) and Astrup et al (1950) has been improved by Astrup and Müllertz (1952) and Brakman (1967). This method is more sensitive to low levels of fibrinolytic activities than the lysis time method. When using the *fibrin plate* method the procedure can be standardized (Ygge 1970).

The fibrinolytic activity in blood, depends on released tissue activator from the endothelial cells (Astrup 1956, Fearnley 1965 and Nilsson et al 1970). The activity is increased after emotional stress, physical exertion, shock, injections of pyrogens and vasoactive drugs (Fearnley 1965).

After venous occlusion the fibrinolytic activity in the blood is increased due to release of tissue activator (Clarke et al 1960, Robertson et al 1971). According to Robertson, who has carried out systematic studies on venous occlusions of the arms and legs, the release of activator depends on the pressure in the occluding cuff and the time during which the cuff is inflated. The venous occlusion method probably is a measure of the fibrinolytic capacity of the venous wall.

The *collection of blood and euglobulin precipitation* have been carried out according to Ygge (1970). After precipitation at pH 6.4 the supernatant was discarded. The precipitate was dissolved in barbital buffer (chapter 3 L) to half the original plasma volume for 5 minutes and then diluted 3:4, 1:2, 3:8 and 1:4 with barbital buffer. The undiluted dissolved precipitate and the dilutions were then tested on fibrin plates.

Determination of fibrinolytic activity. The fibrin plate was prepared as described in chapter 3 L. The same pig heart standard of testing the fibrin plates was also used. 20 µl of each tested solution was placed on a fibrin plate with an Eppendorf automatic pipette. Each solution was tested on two or three plates. After 20 hours incubation at 37°C the lysis areas were measured as described in chapter 3 L. The mean values from the tested solutions were calculated.

Venous occlusion. The occlusion was produced by application of a sphygmomanometer cuff wrapped round the left over arm. The cuff was inflated for exactly 10 minutes to 110 mm Hg. The subject was lying down during the occlusion. Blood samples were obtained from an antecubital vein before application of the cuff and immediately before deflation of the latter. The blood was tested as previously described.

Methodological investigations

The slope of the dilution curves. In 45 patients the spontaneous fibrinolytic activity was studied on two different occasions. Dilution curves of the fibrinolytic activity were determined statistically as regression lines by the aid of a computer with degree of dilution on the abcissa and lysis area on the ordinate.

In order to investigate whether the slopes of the two dilution curves in one patient were approximately identical the following statistical test was performed.

III Platelet count. The platelets were counted in a celloscope (Ljungberg & Co Stockholm Sweden).
Reference value 150.000–450.000 platelets/mikroliter
Abnormal value less than 150.000 plateles/mikroliter

Blood clotting tests

IV Fibrinogen was determined in accordance with Morrison's syneresis method as modified by Blombäck (1958). To prevent lysis of fibrinogen during the analysis, lysine ethylester was added as described by Bergstrom et al (1960)
Reference value 0.2–0.4 g/100 ml
Abnormal value less than 0.2 g/100 ml

V Blood coagulation faktor II VII X was determined with the commercial reagent Simplastin A (General Diagnostic Division, Werner Lambert Morris Plains USA) according to Koran-Bengtsen (1970)
Reference value 70–130 per cent
Abnormal value less than 70 per cent

VI Activated partial thromboplastin time (APTT) was determined with the commercial reagent Platelin plus Activator (General Diagnostic Division, Warner Lambert, Morris Plains, USA.)
Reference value 35–45 seconds
Abnormal value more than 45 seconds

VII Blood coagulation factor VIII (antihemophilic factor A) was determined according to Hardisty and Mac Phersson (1962)
Reference value 50–150 per cent
Abnormal value less than 50 per cent

L A method for determination of fibrinolytic activity in bacterial strains

In chapter 3 E is mentioned how bacterial strains were isolated. Freshly isolated strains of DNAse positive staphylococci (staphylococcus aureus) and group A hemolytic streptococci were grown in TY medium (Holm and Falsen 1967) for 16 hours at 37°C The recultures were kept frozen at −20°C after addition of glycerol.

All bacterial strains were tested during springtime 1972. After thawing the strains were reinoculated in TY medium for 16 hours at 37°C The bacterial growth was estimated by registration of the turbidity in the culture by using a Beckman C spectro photometer The same turbidity was sought to attain in all cultures. The fibrinolytic activity was measured in the clear supernate after centrifugation of the culture at 1500 G for 20 minutes.

For the preparation of *fibrin agar plates* the method of Holmstrom (1965) was employed. Fibrinogen of human origin* was diluted with tris buffer pH 7.5 to a final concentration of 2 g/l (0.2%) The human thrombin used was without detectable amount of plasminogen (Berg et al 1966) and contained 20 N I H units per ml At +40°C 5 ml fibrinogen was mixed with 0.5 ml thrombin and 5 ml agar (2 per cent in tris buffer pH 7.5)

The plate was prepared in a 10 cm plastic Petri dish. After gelification five holes with 4 mm diameter were punched in each agar plate Each basin held 0.017 ml.

Determination of fibrinolytic activity The basins in the fibrin agar plates were filled with the supernates of the centrifuged cultures. The fibrin plates were inoculated at 37°C The diameters of the lysis zones on the plates were then measured at different times of incubation. The final registration was based on the reading performed after 20 hours incubation.

Reference bacterial strain. A wellknown streptokinase producing strain was used as reference bacterial strain (strain H 64 Lancefield group C) The fibrinolytic activity of the culture supernate from this strain was compared with the fibrinolytic activity of the culture supernates from the patient strains. The culture supernate of strain H 64 had a streptokinase activity of 00 units per ml.

Streptokinase reference. A streptokinase preparation (Kabikinas)* was also used as reference The streptokinase preparation was used in different dilutions. The diameters of the lysis zones of these dilutions were compared with the lysis zones of the supernates from the cultures of the patient strains as well as the reference bacterial strain

Classification of the fibrinolytic activity The fibrinolytic activity of the different patient bacterial strains was classified in five groups

0 = no fibrinolytic activity observed

* kindly supplied by AB KABI Stockholm, Swede

+ = fibrinolytic activity demonstrable
++ = fibrinolytic activity less than reference strain H 64
+++ fibrinolytic activity equal to the reference strain H 64
++++ fibrinolytic activity stronger than the reference strain H 64

K. A method for determination of fibrinolytic activity in euglobulin precipitate from blood plasma

The fibrinolytic activity in blood can be demonstrated by different methods. The most physiological method probably is the whole blood clot lysis time. Unfortunately this method is insensitive and can only be used when there is a markedly increased fibrinolytic activity. At low levels of fibrinolytic activity the lysis time is long and the end point reading difficult.

When low levels of fibrinolytic activity are studied it is more suitable to use the euglobulin precipitation method. The euglobulin fraction from plasma is after dilution precipitated at pH 5.2 to 6.4. Most of the fibrinolytic activity is found in the precipitate while most of the fibrinolytic inhibitors remain in the supernate (Kowalski et al 1959, Blix 1964, Ygge 1970).

The fibrinolytic activity in the euglobulin precipitate can be measured in two ways, either as euglobulin clot lysis time or by means of the fibrin plate method. When weak fibrinolytic activity is measured the lysis time is very long by the clot lysis time method and variations in fibrinogen concentrations in the euglobulin fraction interfere with the results (Ygge 1970).

The fibrin plate method which was introduced by Permin (1947, 1950) and Astrup et al (1950) has been improved by Astrup and Mullertz (1952) and Brakman (1967). This method is more sensitive to low levels of fibrinolytic activities than the lysis time method. When using the fibrin plate method the procedure can be standardized (Ygge 1970).

The fibrinolytic activity in blood, depends on released tissue activator from the endothelial cells (Astrup 1956, Fearnley 1965 and Nilsson et al 1970). The activity is increased after emotional stress, physical exertion, shock, injections of pyrogens and vasoactive drugs (Fearnley 1965).

After venous occlusion the fibrinolytic activity in the blood is increased due to release of tissue activator (Clarke et al 1960, Robertsson et al 1971). According to Robertsson, who has carried out systematic studies on venous occlusions of the arms and legs, the release of activator depends on the pressure in the occluding cuff and the time during which the cuff is inflated. The venous occlusion method probably is a measure of the fibrinolytic capacity of the venous wall.

The *collection of blood and euglobulin precipitation* have been carried out according to Ygge (1970). After precipitation at pH 6.4 the supernatant was discarded. The precipitate was dissolved in barbital buffer (chapter 3 L) to half the original plasma volume for 5 minutes and then diluted 3:4, 1:2, 3:8 and 1:4 with barbital buffer. The undiluted dissolved precipitate and the dilutions were then tested on fibrin plates.

Determination of fibrinolytic activity. The fibrin plate was prepared as described in chapter 3 L. The same pig heart standard of testing the fibrin plates was also used. 20 µl of each tested solution was placed on a fibrin plate with an Eppendorf automatic pipette. Each solution was tested on two or three plates. After 20 hours incubation at 37°C the lysis areas were measured as described in chapter 3 L. The mean values from the tested solutions were calculated.

Venous occlusion. The occlusion was produced by application of a sphygmomanometer cuff wrapped round the left over arm. The cuff was inflated for exactly 10 minutes to 110 mm Hg. The subject was lying down during the occlusion. Blood samples were obtained from an antecubital vein before application of the cuff and immediately before deflation of the latter. The blood was tested as previously described.

Methodological investigations

The slope of the dilution curves. In 45 patients the spontaneous fibrinolytic activity was studied on two different occasions. Dilution curves of the fibrinolytic activity were determined statistically as regression lines by the aid of a computer with degree of dilution on the abcissa and lysis area on the ordinate.

In order to investigate whether the slopes of the two dilution curves in one patient were approximately identical the following statistical test was performed.

Reference value 50–150 per cent
Abnormal value less than 50 per cent

I. A method for determination of fibrinolytic activity in bacterial strains

In chapter 3 E is mentioned how bacterial strains were isolated. Freshly isolated strains of DNAse positive staphylococci (staphylococcus aureus) and group A hemolytic streptococci were grown in TY medium (Holm and Falsen 1967) for 16 hours at 37°C The recultures were kept frozen at −20°C after addition of glycerol.

All bacterial strains were tested *during spring* time 1972. After thewing the strains were reinoculated in TY medium for 16 hours at 37°C. The bacterial growth was estimated by registration of the turbidity in the culture by using a Beckman C spectro photometer The same turbidity was sought to attain in all cultures. The fibrinolytic activity was measured in the clear supernate after centrifugation of the culture at 1500 G for ?0 minutes.

For the preparation of *fibrin agar plates* the method of Holmstrom (1965) was employed *Fibrinogen of human origin* was diluted with tris buffer pH 7 5 to a final concentration of 2 g/l* (0 2 %) The human thrombin used was without detectable amount of plasminogen (Berg et al 1966) and contained ?0 N I H units per ml At +40°C 5 ml fibrinogen was mixed with 0 5 ml thrombin and 5 ml agar (? *per cent in tris buffer pH 7 5)*

The plate was prepared in a 10 cm plastic Petri dish. After gellification five holes with 4 mm diameter were punched in each agar plate Each basin held 0.017 ml.

Determination of fibrinolytic activity The basins in the fibrin agar plates were filled with the supernates of the centrifuged cultures. The fibrin plates were inoculated at 37°C The diameters of the lysis zones on the plates were then measured at different times of incubation. The final registration was based on the reading performed after ?0 hours incubation.

Reference bacterial strain. A wellknown streptokinase producing strain was used as reference bacterial strain (strain H 64 Lancefield group C)* *The fibrinolytic activity of the culture supernate* from this strain was compared with the fibrinolytic activity of the culture supernates from the patient strains. The culture supernate of strain H 64 had a streptokinase activity of ?00 units per ml

Streptokinase reference A streptokinase preparation (Kabikinas) was also used as reference The *streptokinase preparation was used in different* dilutions. The diameters of the lysis zones of these dilutions were compared with the lysis zones of the supernates *from the cultures of the patient* strains as well as the reference bacterial strain

Classification of the fibrinolytic activity The fibrinolytic activity of the different patient bacterial strains was classified in five groups

O = *no fibrinolytic activity observed*

* Kindly supplied by AB KABI Stockholm, Sweden

3 mm). The nasal bleedings were treated by application of a piece of gelatine sponge (Spongostan®) soaked with tranexamic acid (Cyklokapron®). The tissue biopsies were stored at −20°C until analyzed.

Solutions (all the reagents were p.a.)

I. *Concentrated extraction solution.* In a flask 10,31 g sodium barbital and 194.36 g potassium thiocyanate were dissolved in 200 ml distilled water. 250 ml 0.1 M hydrochloric acid and 50 ml salt solution (pH = 8.35).
II. *Extraction solution.* Concentrated extraction solution was diluted with equal parts of distilled water.
III. *Salt solution.* In a 1000 ml volumetric flask 4.89 g calcium chloride dihydrate and 2.79 g magnesium chloride hexahydrate and 109.12 g sodium chloride were dissolved in distilled water and diluted to 1000 ml.
IV. *Acid solution.* In 10 ml 1 M hydrochloric acid was dissolved 1.944 g potassium thiocyanate. The solution was prepared daily.
V. *Potassium chloride solution pH 4.2.* To 24 parts 0.15 M potassium chloride solution one part 0.3 M potassium acetate buffer pH 4.2 was added. One part of this solution was neutralized by 0.4 parts of fibrin plate buffer.
VI. *Fibrin plate buffer.* In a 1000 ml volumetric flask 10.31 g sodium barbital was dissolved in 675 ml distilled water and 250 ml 0.1 M hydrochloric acid and 50 ml salt solution were added. The pH was adjusted to 7.75 with 0.1 M hydrochloric acid and the solution diluted to 1000 ml with distilled water.
VII. *Barbital buffer.* Prepared as fibrin plate buffer but without salt solution.
VIII. *Combustion acid.* In 80 ml concentrated sulphuric acid 18 g potassium sulfate, 0.8 g copper sulfate, 2.7 g mercury sulfate and 0.2 g selenium were dissolved by boiling for 4 hours.
IX. *Ninhydrin reagents.* In 12.5 ml ethylenglycol-mono-methylether 0.05 g hydrindantin and 0.33 g ninhydrin were dissolved. To the solution 4.2 ml 4 M sodium acetate buffer pH 5.5 was added. The ninhydrin reagent solution was prepared daily.

Fibrinogen

Bovine fibrinogen was prepared according to Brakman (1967) from citrated plasma. The fibrinogen was stored at −20°C in plastic tubes containing 10 to 25 ml fibrinogen solution in a concentration of 10.5 g fibrinogen per liter, a ionic strength of 0.30* and pH of 7.5.** When fibrin plates were made a tube was defrosted and used after dilution.

Thrombin

Human crude thrombin prepared according to Berg et al (1966) was purified by gel filtration and ion exchange chromatografy (Berg et al 1966). After the chromatografy the thrombin was diluted with distilled water to a concentration of 20 NIH units of thrombin per ml. In the purified thrombin no plasminogen was found (Berg et al 1966).

The procedure to make the fibrin plate

The fibrinogen was filtered through glass wool, diluted with distilled water to ionic strength 0.15 and with fibrin plate buffer to a final fibrinogen concentration of 2 g/liter (0.2 %). The fibrinogen was divided into portions of 3 ml each and mixed with 3 ml fibrin plate buffer and 0.25 ml thrombin solution. The mixture was poured into a Petri glass dish, with a diameter of 10 cm and allowed to clot for one hour. A final fibrinogen concentration of 1 g/liter (0.1 %) gave a firm and opalescent fibrin layer in which the lysis areas were easy to read.

Application of the tissue extract solutions

30 µl of each dilution (1:1, 1:2, 1:3, 1:4, 1:8) was placed on a fibrin plate by means of an Eppendorf automatic pipette. Each tissue extract dilution was tested on three or four different fibrin plates.

Measuring of the lysis areas

After 20 hours incubation at 37°C the lysis areas were measured by means of a microscope (magnitude 6,3 X) with a hair scale in one of the ocular lenses. Two diameters perpendicular to each other were measured and the product of these was taken as the surface area and expressed in mm² (Astrup and Mullertz 1952). Thus the area measured was

* adjusted with distilled water
** adjusted with sodium hydroxide

Let $\Delta + kE$ be the difference between the estimated slopes on occasion one and two in a patient selected at random It is assumed that Δ, the differen e between the exact slopes, is normally distributed with mean u and standard deviation w If the slopes are identical then $u = w = O$ k is a constant which depends on the number of observations on which the estimations are based. E is assumed to be a normally distributed random variable with mean O and standard deviation τ The random variables Δ and E are assumed to be independent.

With the above mentioned postulations, the hypotheses $u = O$ (*t test*) and $w = O$ (*F test*) were tested by use of the values from the patients. Both the hypotheses were accepted on the level $p < 0.05$ This does not mean that $u = O$ and $w = O$ but it means that u and w differ so little from O (compared with τ), that each pair of dilution curves can as a good approximation be regarded as parallel

In 12 patients the dilution curves before and after venous occlusion were tested in the same way The slopes of these dilution curves could also as a good approximation be regarded as parallel

With these tests it has been justified that it is possible to compare dilution curves of one patient.

The presented value of the fibrinolytic activity

On the dilution curves the fibrinolytic activity of *dilution 1 2 was determined statistically and com*pared with the mean values of the measured lysis areas of dilution 1 2. The coefficient of variation between these values was 8 per cent.

The statistically determined lysis areas of dilution 1 2 were presented as the fibrinolytic *activity in euglobulin precipitate from plasma.*

I. A micro method for determination of tissue plasminogen activator in human nasal mucosa

The concentration of plasminogen activator in human tissues varies individually and in different tissues. A high concentration has been found in uterus, adrenals, lymph nodes, prostate and thyroid. Little or no activity at all has been noted in testes, spleen and liver (Albrechtssen 1959 Fearnley 1965 Astrup 1966).

The plasminogen activator can be extracted from the tissue It has been shown to be more or less soluble in *different solutions such as saline* (Macfarlane and Bigg 1948, Astrup and Sterndorff 1956 Albrechtssen 1958) *potassium acetate buf*fers at pH 4 2 (Bachman et al 1964) and potassium thiocyanate (Astrup and Stage 1952).

In 1957 Astrup and Albrechtssen described a method for quantitative determination of acid stable plasminogen activator in tissue. This method is still widely used for determination of tissue activator Large pieces of tissue are however, required and the extraction procedure takes about six hours.

Todd described 1959 a *histochemical semiquantitative method for determination of plasmi*nogen activator This method has since then been used by several other investigators (Kwaan and Astrup 1964 Pandolfi et al 1967 Pettersson 1968 etc) *By Todd's method it has been found that* plasminogen activators are localized in the endothelial cells in the capillaries and the small veins

A comparison between Todd's method and the present method by use *of biopsies from human* carcinomatosis (Petterson et al 1973) showed a good correlation.

Nasal mucosa is suitable for tissue plasminogen activator studies because it is easy to take biopsies from the tissue which is very rich in capillaries and small veins (Batson 1954).

Studies of tissue plasminogen activator in nasal mucosa have *previously been carried out by use of* saline extraction (Sasaki et al 1959) and potassium thiocyanate extraction (Buch Rasmussen 1966). In none of these studies has the plasminogen activator been determined quantitatively

The purpose of this investigation was to work out a quantitative method for determination of tissue plasminogen activator in small pieces of human nasal mucosa (3–5 mg).

Material and methods

Tissues

1 Postmortal nasal mucosa was obtained from eight bodies. The *inferior concha on one or both* sides were removed within three hours after death The nasal mucosa was divided into small pieces, which were stored at − 0°C

2. On living subjects 3–5 mg nasal mucosa biopsies were *taken without anesthesia from the* inferior concha by a Hartman ear polyp forceps (()

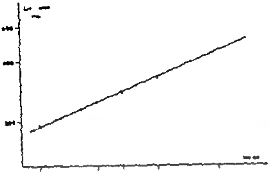

Figure 7. Standard curve. On two different occasions, frozen supernatants from three different tubes of lyophilized pig heart standard were diluted with extraction solution. On the first occasion each dilution was tested on three different fibrin plates and on the second occasion on six different fibrin plates. A total of 27 incubations were made with each dilution (1:1, 1:2, 1:3, 1:4 and 1:8). The mean values from each of these 27 incubations were calculated and a standard curve was drawn on double logarithmic paper with degree of dilution on the abscissa and the lysis areas in mm² on the ordinate. On the abscissa was also plotted the units of pig heart units (PHU) per ml.

The standard curve was also statistically estimated as regression line according to the least square method Y = 174 + 274X. The correlation coefficient between dilution and lysis area was 0.99.

Dilution	Lysis area mm² (mean value of 27 determinations)	± S.D.	Variation coefficient (± S.D. in per cent)
1:1	439	40	9 %
1:2	323	23	%
1:3	274	24	9 %
1:4	231	27	11 %
1:8	193	23	12 %

lysis area given by one mg lyophilized pig heart standard.

The standard curve

The construction of the standard curve is described in figure 7. It was used as long as the same fibrinogen preparation was used. Each day the standard curve was checked with pig heart standard supernatant. If the mean value of six incubations was within the limit 441 ± 48 mm² the standard curve was accepted.

The pig heart standard supernatant was tested against urokinase (Leo Pharmaceutical Products, Denmark.) With the fibrinogen used in the experiments 6.3 PHU gave the same lysis area on the fibrin plates as 2 Ploug units of urokinase. (Three different tubes with 2.400 Ploug units of urokinase were diluted with fibrin plate buffer to 2 Ploug units of urokinase per ml. The mean value of six incubations from each dilution was calculated.)

Method for determination of tissue plasminogen activator

Total activity

The nasal mucosa was weighed and 0.5 ml distilled water per mg of tissue added. Homogenisation was carried out in a Potter glass homogenisator at +4°C for 4 minutes at a speed of 500 rpm. Two samples containing 100 µl each were then taken for nitrogen determination. To the rest of the suspension an equal part of concentrated extraction solution was added. The suspension was homogenised for a further one minute and then centrifuged at +4°C for 20 minutes at 1700 G. The sediment was discharged and the supernatant was divided into two portions. One of the portions was diluted with extraction solution (1:1, 1:2, 1:3, 1:4, 1:8) and the dilutions were incubated on fibrin plates.

Acid stable activity

The other portion of the supernatant was treated with acid. To each ml was added 0.5 ml of the acid solution to give a pH of 1.0. After 15 minutes the solution was neutralized with 0.1 g sodium bicarbonate and dilutions with extraction solution (1:1, 1:2, 1:3, 1:4 and 1:8) were made and incubated on fibrin plates.

After 20 hours incubation at 37°C the lysis areas on all fibrin plates were measured.

From each dilution 3 or 4 incubations were made; the mean values of these lysis areas were calculated for both total activity and acid stable activity. The mean values were then plotted on double logarithmic paper with degree of dilution on the abscissa and the mean values of the lysis areas on the ordinate.

The nitrogen concentration was determined in the suspension and the lysis area, corresponding to a nitrogen concentration of 0.10 mg nitrogen per

the area of the circumscribed square The mean value of the three or four samples of each dilution was calculated and a curve with the degree of dilution on the abscissa and the lysis areas in mm^2 on the ordinate was drawn on double logarithmic paper

Plasminogen free fibrin plate

According to Lassen (1952) the previously described fibrin plate was heated for 35 minutes at 85°C

Another type of plasminogen free fibrin plate was made with plasminogen free fibrinogen and thrombin (Ygge 1970).

Determination of nitrogen in the tissue extract

Nitrogen was determined according to Strid (1961) as modified by Rybo (1966). To 100 µl of a nasal mucosa extract was added 100 µl of the combustion acid.

The mucosa extract and the acid were heated at 400°C for 18 hours on a sand bath After cooling 3 ml 4 M sodium acetate buffer pH 5 5 and 7 ml distilled water were added. Samples of 2 ml were then taken to carry out the ninhydrin reaction. To each 2 ml was added 1 ml ninhydrin reagents. The solution was shaken and the tube was then placed in a boiling water bath for 15 minutes. After cooling 10 ml 50 per cent ethanol was added. The tube was again shaken and the colour determined in a Beckman spektro-photo-meter at 570 nm, with water as a reference

Ammonium sulphate solution containing 1 µg per µl was used as a standard.

To test the error of the nitrogen determination method three different nasal mucosa extracts were made From each extract six samples were analysed. The coefficients of variation in these three extracts were 2.9 3 0 and 3 6 per cent respectively

Standard

Standard tissue plasminogen activator prepared from pig heart (Astrup and Albrechtsen 1957) was kindly supplied by AB KABI Sweden With one or two months intervall a tube with lyophilided pig heart standard was dissolved (6 mg powder per ml extraction solution) The suspension was homogenised in a Potter glass homogenisator at +4°C for 4 minutes at a speed of 500 rpm and then centrifuged at +4°C for 0 minutes at 1700 G. The supernatant was divided into small plastic tubes (one ml in each) and stored at −80°C

In order to investigate whether the fibrinolytic activity in the frozen supernatants changed, when stored at −80°C one batch of tubes with the same frozen supernatant was tested during a period of five months. On 19 different days incubations on fibrin plates were made with the undiluted supernatant (table 3) The mean values of the lysis area was calculated for each day When the mean values from these 19 days were tested with the mean square successive difference test (Brownlee 1965) no significant difference ($p > 0.05$) was found between the mean values.

Frozen supernatants from five different tubes of lyophilized pig heart standard were tested on 69 different days (table 3). Each day as a rule six incubations were made with one of the defrosted undiluted supernatants. The total mean value of the lysis areas from these 69 days was 441 mm with a standard deviation of 48 mm

Pig heart unit (PHU)

Astrup and Albrechtsen (1957) defined one unit pig heart standard plasminogen activator as the

Table 3 Frozen supernatants from five different tubes of lyophilized pig heart standard were tested on 69 different days.

lysis are given by one mg lyophilized pig heart standard.

The standard curve

The construction of the standard curve is described in figure 7. It was used as long as the same fibrinogen preparation was used. Each day the standard curve was checked with pig heart standard supernatant. If the mean value of six incubations was within the limit 441±48 mm^2 the standard curve was accepted.

The pig heart standard supernatant was tested against urokinase (Leo Pharmaceutical Products, Denmark.) With the fibrinogen used in the experiments 6.3 PHU gave the same lysis area on the fibrin plates as Ploug units of urokinase. (Three different tubes with ...400 Ploug units of urokinase were diluted with fibrin plate buffer to ? Ploug units of urokinase per ml. The mean value of six incubations from each dilution was calculated.)

Method for determination of tissue plasminogen activator

Total activity

The nasal mucosa was weighed and 0.5 ml distilled water per mg of tissue added. Homogenisation was carried out in a Potter glass homogenizator at +4°C for 4 minutes at a speed of 500 rpm. Two samples containing 100 μl each were then taken for nitrogen determination. To the rest of the suspension an equal part of concentrated extraction solution was added. The suspension was homogenised for a further one minute and then centrifuged at +4°C for 20 minutes at 1700 G. The sediment was discharged and the supernatant was divided into two portions. One of the portions was diluted with extraction solution (1:1, 1:..., 1:3, 1:4, 1:8) and the dilutions were incubated on fibrin plates.

Acid stable activity

The other portion of the supernatant was treated with acid. To each 2 ml was added 0.5 ml of the acid solution to give a pH of 1.0. After 15 minutes the solution was neutralized with 0.1 g sodium bicarbonate and dilutions with extraction solution (1:1, 1:2, 1:3, 1:4 and 1:8) were made and incubated on fibrin plates.

After 20 hours incubation at 37°C the lysis areas on all fibrin plates were measured.

From each dilution 3 or 4 incubations were made, the mean values of these lysis areas were calulated for both total activity and acid stable activity. The mean values were then plotted on double logarithmic paper with degree of dilution on the abscissa and the mean values of the lysis areas on the ordinate.

The nitrogen concentration was determined in the suspension and the lysis area, corresponding to a nitrogen concentration of 0.10 mg nitrogen per

the area of the circumscribed square. The mean value of the three or four samples of each dilution was calculated and a curve with the degree of dilution on the abscissa and the lysis areas in mm^2 on the ordinate was drawn on double logarithmic paper

Plasminogen free fibrin plate

According to Lassen (1952) the previously described fibrin plate was heated for 35 minutes at 85°C.

Another type of plasminogen free fibrin plate was made with plasminogen free fibrinogen and thrombin (Ygge 1970)

Determination of nitrogen in the tissue extract

Nitrogen was determined according to Strid (1961) as modified by Rybo (1966). To 100 μl of a nasal mucosa extract was added 100 μl of the combustion acid.

The mucosa extract and the acid were heated at 400°C for 18 hours on a sand bath After cooling 3 ml 4 M sodium acetate buffer pH 5 5 and 7 ml distilled water were added. Samples of 2 ml were then taken to carry out the ninhydrin reaction. To each 2 ml was added 1 ml ninhydrin reagents. The solution was shaken and the tube was then placed in a boiling water bath for 15 minutes. After cooling 10 ml 50 per cent ethanol was added. The tube was again shaken and the colour determined in a Beckman spektro-photo-meter at 570 nm with water as a reference

Ammonium sulphate solution containing 1 μg per μl was used as a standard.

To test the error of the nitrogen determination method three different nasal mucosa extracts were made From each extract six samples were analysed. The coefficients of variation in these three extracts were 2.9 3.0 and 3.6 per cent respectively

Standard

Standard tissue plasminogen activator prepared from pig heart (Astrup and Albrechtssen 1957) was kindly supplied by AB KABI Sweden. With one or two months intervall a tube with lyophilided pig heart standard was dissolved (6 mg powder per ml extraction solution). The suspension was homogenized in a Potter glass homogenisator at +4°C for 4 minutes at a speed of 500 rpm and then centrifuged at +4°C for 20 minutes at 1700 G. The supernatant was divided into small plastic tubes (one ml in each) and stored at −80°C

In order to investigate whether the fibrinolytic activity in the frozen supernatants changed when stored at −80°C one batch of tubes with the same frozen supernatant was tested during a period of five months. On 19 different days incubations on fibrin plates were made with the undiluted supernatant (table 3) The mean values of the lysis area was calculated for each day When the mean values from these 19 days were tested with the mean square successive difference test (Brownlee 1965), no significant difference ($p > 0.05$) was found between the mean values.

Frozen supernatants from five different tubes of lyophilized pig heart standard were tested on 69 different days (table 3). Each day as a rule six incubations were made with one of the defrosted undiluted supernatants. The total mean value of the lysis areas from these 69 days was 441 mm^2 with a standard deviation of 48 mm

Pig heart unit (PHU)

Astrup and Albrechtssen (1957) defined one unit pig heart standard plasminogen activator as the

Table 3 Frozen supernatants from five different tubes of lyophilized pig heart standard tested on 69 different days

	Batch number 1	2	3	4	5	Total

lysis area given by one mg lyophilized pig heart standard.

The standard curve

The construction of the standard curve is described in figure 7 It was used as long as the same fibrinogen preparation was used. Each day the standard curve was checked with pig heart standard supernatant. If the mean value of six incubations was within the limit 441±48 mm^2 the standard curve was accepted.

The pig heart standard supernatant was tested against urokinase (Leo Pharmaceutical Products, Denmark.) With the fibrinogen used in the experiments 6.3 PHU gave the same lysis area on the fibrin plates as 2 Ploug units of urokinase. (Three different tubes with ~400 Ploug units of urokinase were diluted with fibrin plate buffer to

Ploug units of urokinase per ml. The mean value of six incubations from each dilution was calculated.)

Method for determination of tissue plasminogen activator

Total activity

The nasal mucosa was weighed and 0.5 ml distilled water per mg of tissue added. Homogenisation was carried out in a Potter glass homogenizator at +4°C for 4 minutes at a speed of 500 rpm. Two samples containing 100 µl each were then taken for nitrogen determination. To the rest of the suspension an equal part of concentrated extraction solution was added. The suspension was homogenised for a further one minute and then centrifuged at +4°C for 20 minutes at 1700 G. The sediment was discharged and the supernatant was divided into two portions. One of the portions was diluted with extraction solution (1 1 1 2, 1 3 1 4 1 8) and the dilutions were incubated on fibrin plates.

Acid stable activity

The other portion of the supernatant was treated with acid. To each 2 ml was added 0.5 ml of the acid solution to give a pH of 1 0. After 15 minutes the solution was neutralized with 0.1 g sodium bicarbonate and dilutions with extraction solution (1 1 1 2, 1 3 1 4 and 1 8) were made and incubated on fibrin plates.

After 20 hours incubation at 37°C the lysis areas on all fibrin plates were measured.

From each dilution 3 or 4 incubations were made the mean values of these lysis areas were calculated for both total activity and acid stable activity The mean values were then plotted on double logarithmic paper with degree of dilution on the abscissa and the mean values of the lysis areas on the ordinate.

The nitrogen concentration was determined in the suspension and the lysis area, corresponding to a nitrogen concentration of 0.10 mg nitrogen per

ml nasal mucosa extract was read from the dilution curves.

The lysis area corresponding to 0.10 mg N per ml of the total activity was read on the standard curve the value was multiplied by ten and presented as PHU per mg nitrogen in the nasal mucosa.

The lysis area corresponding to 0.10 mg nitrogen of the acid stable activity was read on the standard curve. The value obtained was multiplied by 1 25 to compensate for the dilution with acid. To get activity per mg nitrogen the value was multiplied by ten. This compensated value was presented as PHUs per mg nitrogen in the nasal mucosa.

Experiments and results

In each experiment three or four incubations of each dilution (1 1 1 2, 1 3 1 4 1 8) were tested. In the experiments presented in table 5–9 and in figure 8 no nitrogen determinations were carried out. In these experiments the mean values of the lysis areas in the undiluted solutions were read on the standard curve and are presented as PHU in the tables.

Extraction

1 Extraction solutions

The results of the extractions with 2 M and 0.15 M *potassium thiocyanate and 2 M and 0.15 M so-* dium chloride at pH 7 0 and 0.15 M potassium chloride at pH 4 2 are shown in table 4.

The highest fibrinolytic activity was observed when 2 M potassium thiocyanate was used.

2 Ultra sonic extraction

A piece of nasal mucosa was homogenised with 0.15 M sodium chloride for 15 minutes and then treated with ultra sonic, 250 W for one hour in a thin plastic tube. When tested on fibrin plates the undiluted suspension gave a lysis area of 100 mm^2 after centrifugation the undiluted supernatant gave a lysis area of 30 mm^2. The sediment was dissolved in 2 M potassium thiocyanate shaken for *one hour and then centrifuged. The supernatant* obtained undiluted gave a lysis area of 570 mm^2.

3 Homogenisation time

After 15 minutes homogenising time (table 5) there was a decrease in activity after 30 minutes the decrease was more pronounced. For routine purpose a homogenising time of 4 + 1 minutes at a speed of 500 rpm is chosen.

4 Shaking time

As shown in table 6 it is not necessary to shake the tissue suspensions after homogenisation.

Table 5 Homogenising time. A piece of nasal mucosa was homogenised for different lenghts of time at +4°C at a speed of 500 r.p.m. After 2 5 15 and 30 minutes, samples were taken from the tissue suspension. The samples were centrifuged at +4°C for 20 minutes (1 700 G) and the supernatant then tested on fibrin plates. The lysis areas, expressed as PHU given by *different homogenisation time (minutes) are presented*

	Homogenisation time in minutes			
	2	5	15	30
Experiment 1		46	21	10
2		83	69	48
3	83	75	66	43
4	33	37	29	
5	81	78	83	

Table 4 Effectivity of different extraction solutions. Nasal mucosa was divided and homogenised with the same proportion of the different extraction solutions in *the first three experiment. Equal parts of pig h [illegible]* weight) were used in the fourth experiment.

After 5 minutes homogenisation at 500 r.p.m. and +4°C the samples were centrifuged at +4°C for [illegible] 1 700 G. The potassium chloride solution was then neutralized by 0 4 part of the fibrin plate buffer and tested on fibrin plates together with *the undiluted supernatants from the other extraction*. Lysis areas in mm^2 (mean [illegible]) of the different extraction solutions are presented

	2 M KSCN	0.15 M KSCN	M NaCl	0 15 M NaCl	0 15 M KCl pH 4
Experiment 1	430	90	0	130	3 0
2	595				330
3	670				146
4	484				

Table 6. Shaking time. A piece of nasal mucosa was homogenised for 5 minutes, the tissue suspension was then divided into samples, which were shaken for different length of time at +4°C. The suspensions were centrifuged at +4°C for 20 minutes (1 700 G) and the supernatants tested on fibrin plates. The lysis areas, expressed as PHU at different shaking times, are presented

	Shaking time minutes 0	5	15	30	60	hours 4
Experiment 1		49	51	48	50	51
2	48		42			
3	94		90			

5. Number of extractions

On 51 different occasions a second extraction was made. After homogenising for 5 minutes, the sediment after centrifuging was dissolved in the original volume of extraction solution and shaken at +4°C. After centrifuging the supernatant was tested on fibrin plates. The average activity was 1.2 per cent of the activity in the first extraction.

Thus when small pieces of nasal mucosae are homogenised only one extraction is necessary. Prolonged shaking and further extractions did not give essentially more yield of fibrinolytic activity.

Experiments on acid treatment

6. The correlation between total activity and acid stable activity

On 104 different pieces of nasal mucosa, taken from living subjects, the total activity and the acid stable activity have been determined according to the method described. In none of the determinations was the acid stable activity larger than the total activity. The regression line which describes the relationship between the total activity and the acid stable activity was graphically estimated and was shown to be well approximated by a straight line through the origo. The correlation coefficient between total and acid stable activity was 0.93.

7. Fibrinolytic activity in the tissue extract supernatant and sediment after acid treatment

Supernatants of homogenised nasal mucosa were treated with acid for 15 minutes at different pH. After centrifugation the sediments were dissolved and neutralized and the supernatants dialysed with extraction solution (table 7). After the dialysis the increase of weight of the dialysed supernatant was about four per cent.

As shown in table 7 the dissolved sediments and the dialysed supernatants both contained fibrinolytic activity after acid treatment.

8. Duration of acid treatment

Samples from supernatants of homogenized nasal mucosa were treated with acid solution at pH 1.0 for different lengths of time (table 8). As shown in table 8, the duration of acid treatment, up to 24 hours, seems to be of no importance. For routine purpose 15 minutes is chosen.

Table 7. Fibrinolytic activity in supernatant and sediment after acid treatment. Supernatants of nasal mucosa homogenate were divided into two portions of 4 ml. To each one of the portions acid solution was added to obtain pH 1.2, 1.0, 0.8 or 0.6. After 15 minutes at +4°C the acidified portions were centrifuged at 20 000 G for 20 minutes at +4°C. The sediment were dissolved in 4 ml extraction solution and neutralized with sodium bicarbonate. The supernatants were neutralized by repeated dialysis in large volumes of extraction solution. The dissolved sediments and the dialysed supernatants were tested on fibrin plates. The lysis areas, expressed as PHU are presented

	pH 1.2 sed	pH 1.2 sup	pH 1.0 sed	pH 1.0 sup	pH 0.8 sed	pH 0.8 sup	pH 0.6 sed	pH 0.6 sup

9 Dilution of the tissue extract supernatant before acid treatment

Supernatants of nasal mucosa homogenate were divided into portions. Two of the portions were not diluted. The other portions were diluted with distilled water or with extraction solution.

After acidification and neutralisation (table 9) the highest fibrinolytic activity was generally found in the portions which were not diluted before the acidification.

Table 9 Dilution of tissue extract supernatant before acid treatment A piece of nasal mucosa was homogenized and centrifuged. The superna tant was divided into por tion of 2 mL Two of the portions (1 and 2) were not diluted The other portions were *diluted 1.3* (portion number 3) or 1 7 (4) with distilled water and 1.3 (5) or 1 7 (6) w th extraction solution. To all the portions acid solution was added to pH 1 0 After 15 minutes t +4°C the undiluted portion (1) was neutralized with sodium bicarbonate the other portions were centrifuged at +4°C fo 20 minutes at 20 000 G The sediments were dissolved in 2 ml extra tion olution neutralized with sodium bicarbonate and tested on fibrin plates together with portion one The lysis areas, expressed as PHU are presented

(figure 8)

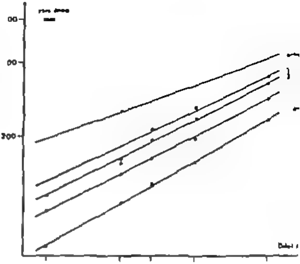

Figure 8 In the figure are shown the dil tion curve experiment II in table 9 The number of the curves is same as the number of the p rtions in table 9 Contr the untreated centrifuged homogenate The portion which was not diluted before centrifugation was teste two ways. After centrifuging the sediment was dissol and neutralized (7) and the supernatant was dialysed extraction solution (8).

10. Accuracy in reproduction when testing p mortal nasal mucosa

On eight different occasions pieces from the sa frozen nasal mucosa were analyzed according the described method (table 10 and figure 9).

Determinations of the fibrinolytic activity w made in two different ways With the aid o computer a *dilution curve was statistically e* mated as a regression line according to the le square method with the logarithmic values of t dilutions on the abscissa and the logarithmic valu of the mean values of the lysis areas in t *different dilutions on the ordinate On the line t* lysis area corresponding to 0 10 mg nitrogen p ml nasal mucosa extract was numeri ally dete mined by the computer (column II table 10)

A second determination was made graphically A graph was plotted on double logarithmic pap (as a regression line according to the lea t squa method) with the dilutions on the abscissa and th mean values of the lysis areas in the five diluti n on the ordinate The lysis area rresp nding t 0.10 mg nitrogen was read on the graph (lu n III and IV in table 10, figure 9)

The graphically determined lysis area f t total acti ity corresponding to 0 10 mg nitrogen

Table 10. Accuracy in reproduction when testing post mortal nasal mucosa Eight pieces from the same frozen nasal mucosa were analysed according to the described method. The nitrogen concentration was determined in each tissue extract (I). The lysis area of the total activity corresponding to 0.10 mg nitrogen per ml nasal mucosa homogenate was determined by computer (II) and graphically (III). The lysis area of the acid stable activity corresponding to 0.10 mg nitrogen per ml nasal mucosa homogenate was determined graphically (IV). The values of the lysis areas in (III) and (IV) were read on the standard curve and expressed as PHU and PHUs per mg nitrogen in the nasal mucosa homogenate. The quotient, expressed in per cent, between the acid stable activity and the total activity was called the tissue activator quotient

Day of experiment	Nitrogen concentration mg per ml nasal mucosa homogenate (I)	Lysis area at 0.10 mg N per ml nasal mucosa homogenate (II)	(III)	(IV)	Total activity PHU/mg N	Acid stable activity PHUs/mg N	Tissue activator quotient in per cent
701202	0.104	434	420		54		
701202	0.119	431	450		[illegible]		
701117	0.220	382	385		46		
701116	0.070	407	420	340	54	45	83
701103	0.170	407	415	340	53	45	85
701103	0.142	416	415	330	53	43	81
701029	0.092	461	460	370	63	54	86
701026	0.088	411	420	360	54	50	93
	Mean value	417	423	348	55	47	86
	± S D	[illegible]	23	16	5	5	4
	Variation coefficient (2 S D in per cent)	5	5	5	10	10	5

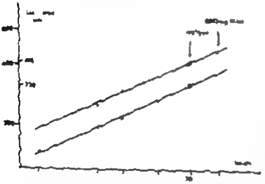

Figure 9. Experiment number 6 (701103) in table 10. The nitrogen concentration in the undiluted tissue extract was 0.284 mg nitrogen per ml. As the tissue extract is diluted once the nitrogen concentration in the undiluted supernatant corresponds to 0.142 mg nitrogen per ml. When the supernatant is diluted to 70.4 per cent it corresponds to 0.10 mg nitrogen per ml of the original extract. The lysis areas of the total activity (curve 1) and the acid stable activity (curve 2) at 0.10 mg nitrogen per ml are read on the ordinate

per ml nasal mucosa extract was read on the pig heart standard curve and expressed as PHU per mg nitrogen. The acid stable activity was expressed in the same way as PHUs per mg nitrogen

The variation coefficient of the total activity (graphical values), measured as PHU and of acid stable activity measured as PHUs, were 10 per cent. As shown in table 10 it is not necessary to use numerical determinations for routine use

11. Influence of admixture of plasma in nasal mucosa

Different plasmas with a high fibrinolytic activity were added to supernatants of nasal mucosa homogenate. The plasmas used were taken immediately after half an hours heavy exercise on a test bicycle to receive an increased fibrinolytic activity in the plasmas, and frozen at −20°C for about one month.

The amount of plasma correspond approximately to seven times the amount of nasal mucosa wet weight/wet weight. The lysis areas were about the same, irrespective of whether plasma was added or not (table 11). Thus even large amounts of plasma with a high fibrinolytic activity did not change the tissue plasminogen activator activity

Experiments on the fibrin plates

12. The importance of different fibrinogen preparations

Fibrin plate were made with different fibrinogen solutions and tested with nasal mucosa extract supernatants

Table 8 Duration of acid treatment A supernatant of nasal mucosa homogenate was treated with acid solution to pH 1 0 After 5 and 15 minutes, 1 4 6 and 24 hours at +4°C samples were taken from the acidified solution *neutralized with sodium bicarbonate* and tested on fibrin plates. The lysis areas, expressed as PHU are presented

10. Accuracy in reproduction when testing post mortal nasal mucosa

On eight different occasions pieces from the same frozen nasal mucosa were analyzed according to the described method (table 10 and figure 9).

Determinations of the fibrinolytic activity were made in two different ways. With the aid of a computer a dilution curve was statistically estimated as a regression line according to the least square method with the logarithmic values of the dilutions on the abscissa and the logarithmic values of the mean values of the lysis areas in the different dilutions on the ordinate On the line the lysis area corresponding to 0 10 mg nitrogen per ml nasal mucosa extract was numerically determined by the computer (column II table 10)

A second determination was made graphically A graph was plotted on double logarithmic paper (as a regression line according to the least square method) with the dilutions on the abscissa and the *mean values of the lysis areas in the the dilutions* on the ordinate *The lysis area corresponding to 0.10 mg nitrogen* was read on the graph (column *III and IV in table 10, figure 9)*

The graphically determined lysis area of the total activity corresponding to 0 10 mg nitrogen

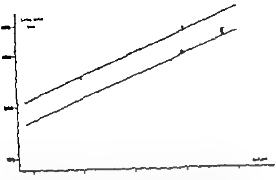

Figure 10 The importance of different buffers in the fibrin plate Fibrin plates were made, according to the method described, with two different buffers. The plates were tested with nasal mucosa extract supernatant.
Buffer I. Fibrin plate buffer, containing salt solution with Mg^{++} and Ca^{++} in physiological concentrations.
Buffer II Barbital buffer without the salt solution.
Dilution curves of the two types of fibrin plates are presented.

14 The importance of different buffers

Fibrin plates were made with two different buffers (fibrin plate buffer and barbital buffer) and tested with nasal mucosa extract supernatants.

As shown in figure 10, the highest fibrinolytic activity was observed when a buffer containing Ca^{++} and Mg^{++} in physiological concentrations was used. This buffer was used in the experiments.

15 The importance of different concentrations of agar

Fibrin plates were made without agar and with agar in different concentrations. The different fibrin plates were tested with a nasal mucosa extract supernatant.

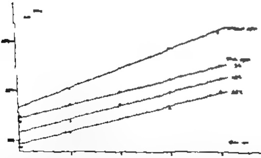

Figure 11 The importance of different concentrations of agar in the fibrin plate Fibrin plates were made, according to the method described, without agar and with agar in 0.5 1 and per cent. The plates were tested with nasal mucosa extract supernatant. Dilution curves of the four types of fibrin plates are presented.

As shown in figure 11 the highest fibrinolytic activity was noted in the fibrin plates without agar

16. Plasminogen free fibrin plates

On two different occasions fibrin plates were made as described and then heated to 85°C for 35 minutes. Unheated and heated fibrin plates were tested with pig heart standard supernatant and nasal mucosa extract supernatant.

Plasminogen free fibrin plates according to Yggs (1970) were also made and tested in the same way

No lysis areas were seen on the heated fibrin plates or on the plasminogen free fibrin plates. Thus the supernatants do not contain any detectable amount of plasmin.

Comments

Mainly two methods are used for determination of tissue plasminogen activators, Astrup and Albrechtsen's method (1957) and Todd's method (1959). When using Astrup and Albrechtsen's method 100–1000 mg tissue is required and the extraction takes about six hours. Todd's method can be used to analyse small pieces of tissue but is only semiquantitative. The results of the experiments in this investigation have shown that it is possible to simplify and modify Astrup and Albrechtsen's method and to make it suitable for quantitative analysis of small pieces of nasal mucosa.

Astrup and Albrechtsen correlated the fibrinolytic activity to the wet weight of the tissue In the present method small pieces of nasal mucosa are used. These pieces dry quickly and the weight loss is of importance. The fibrinolytic activity was therefor correlated to the nitrogen concentration in the nasal mucosa and not to wet weight.

In Astrup and Albrechtsen's method the tissue extract supernatant, after dilution, was acidified with 1 M hydrochloric acid to pH 1 0 and then centrifuged. The sediment was dissolved in 2 M potassium thiocyanate and neutralized with sodium bicarbonate. The sediment was supposed to contain all the activators, and the supernatant to contain the inhibitors. To prove this hypothesis

Table 11 Influence of admixture of plasma in nasal mucosa. Biopsies of nasal mucosa taken from living subjects were homogenized and the nitrogen concentration determined After centrifuging each supernatant was divided into two portion of 3 ml each. To one portion was added 20 μl plasma with a high fibrinolytic activity Both protions were then analysed according to the described method The total activity is expressed as PHU per mg nitrogen and the acid stable activity as PHUa per mg nitrogen of the nasal mucosa homogenate The fibrinolytic activity in euglobulin precipitate from plasma was determined as described in chapter 3 k.

Experiment number	Plasma number	Lysis area of euglobulin precipitate from plasma	Nasal mucosa number	Total activity PHU	Acid stable activity PHUa	Plasma added Total activity PHU	Plasma added Acid stable activity PHUa
1	I	320 mm^2	1	63	39	67	44
	II	350	1	69	44	66	41
3	I	320	2	59	21	53	19
4	III	270	3	99	–	99	–

As shown in table 12 the highest fibrinolytic activity was observed when human fibrinogen prepared according to Brakman (1967) was used. *Bovine fibrinogen prepared according to Brakman* (1967) gave about the same lysis areas as human fibrinogen produced by AB KABI Stockholm Sweden. Bovine fibrinogen from AB KABI Stockholm Sweden was not sufficiently sensitive for the analyses.

For routine use fibrin plates were made with bovine fibrinogen prepared according to Brakman. Human fibrinogen was not used for economical reasons.

Six different bovine fibrinogen preparations have been prepared according to Brakman during two years. These six preparations have given about the same lysis areas when tested with the pig heart standard.

Table 12 The importance of different fibrinogen preparations Fibrin plates were made according to the method described with four different fibrinogen solutions. Fibrinogen concentration in the plate was 1 g per liter (0.1 %) The plates were tested with nasal mucosa extract supernatants.

Fibrinogen I Bovine fibrinogen prepared according to Brakman (1967).
II Human fibrinogen prepared according to Brakman (1967). Three different preparations were tested

13 The importance of different thrombin preparations

Fibrin plates were made with three different thrombin solutions and tested with nasal mucosa extract supernatants.

As shown in table 13 a slightly higher activity was noted when Topostasin was used. Human crude thrombin before and after gel filtration and ion exchange chromatography gave about the same lysis areas. *Despite the larger lysis areas received* by using Topostasin, purified human thrombin was used instead of Topostasin, which contains plasminogen in different concentrations (Shulte 1965 Berg et al 1966).

Table 13 The importance of different thrombin preparations. Fibrin plates were made according to the method described with three different thrombin solutions, each containing 20 NIH units of thrombin per ml The plate were tested with nasal mucosa extract supernatant

CHAPTER 4

RESULTS

A. The frequency of epistaxis

The frequency of epistaxis was studied in the population sample, the out patients and the hospitalized patients (chapter) by using the answers to questions numbers 5 6 7 and 9 in the questionnaire (chapter 3 A) for statistical analyses.

Results

The incidence of epistaxis in the population. In the population sample was noted that 60 per cent of the subjects (246/410) had suffered from epistaxis at least once in life (appendix 1).

It was also found that 15 per cent of the men (28/190) and 9 per cent of the women (20/220) had single or several bleedings from the nose every year. The difference in frequency between the sexes is not significant ($0.10 > p > 0.05$).

During the week immediately preceding the week in which the questionnaire was answered 9 subjects (2.2 %) in the population sample had had epistaxis (table 14). All these nine subjects belonged to the group wh had single or several bleedings every year none of them had been treated for epistaxis by doctor.

Habitual bleeders. Subjects and patients who said they had several episodes of epistaxis every year were called habitual bleeders. In all age groups there was a higher proportion of habitual bleeders in the out patients than in the population sample (figure 12).

The habitual bleeders constituted 4 per cent of the population sample 2 per cent of the out patients and 8 per cent of the hospitalized patients (appendix 1). Among the out patients the highest proportion of habitual bleeders was observed in the age group less than 20 years old (figure 12).

Subjects treated for epistaxis. In the population sample 4 subjects (6 %) had at least once been treated for epistaxis by a doctor.

Out of 18 habitual bleeders in the population sample, 14 subjects (78 %) had never been treated for epistaxis by a doctor.

Patients treated for epistaxis. Of the out patients 17 per cent and of the hospitalized patients 39 per cent had epistaxis for the first time in life.

By use of the sex and age distribution in the out patients and the inhabitants of Goteborg it was possible to calculate the frequency of subjects

Table 14. A ue subjects in the population sample ith epistaxis the previous eek. The answers to question numbers 1 to 5 and 7 to 9 in the questionnaire (chapter 3 A) are presented. Astrup and Albrechtssen mixed a pig heart activator solution with an ox lung inhibitor (pulmin) solution. They were able to separate this particular activator from this particular inhibitor by acid precipitation. When the mixture of activator and inhibitor was tested on fibrin plates, they showed that the undiluted mixture gave no lysis but that a lysis area was obtained when the mixture was diluted. The inhibitor thus seemed to have its highest inhibition activity in undiluted solutions.

In none of the determinations of total and acid stable activity in this study has it been possible to demonstrate inhibitors which react like pulmin. The activity in the undiluted solutions has always been higher than in the diluted solutions. If there are inhibitors present in the tissue extract supernatants they seem to have the same inhibition activity in undiluted as in diluted solutions.

When the tissue extract supernatants were *precipitated with acid both the neutralized sediments* and the dialysed supernatants contained activity. The activity therefor must be determined on both the sediments and supernatants. The precipitations have not in any experiment been complete there has always been activity in the dialysed supernatants. Dilution before acid precipitation did not improve the results.

Experiments which were carried out with nasal mucosa have shown that the highest fibrinolytic activity was obtained always when the tissue extract supernatants were tested without acid treatment. Acid treatments always destroyed a varying part of the total activity.

The experiment with ultra sonic extraction showed that the activity in the nasal mucosa was low even if all the cell membranes were destroyed. When the tissue extract was treated with potassium thiocyanate the activator was either released from the tissue extract or the inhibitors were already destroyed at this moment.

Previous investigators (Astrup and Albrechtssen 1957 Rybo 1966 Brakman 1967) prepared a standard curve every day. The variation coefficient between the slopes of the dilution curves from different days in the investigations mentioned were 12 to 16 per cent and between the lysis areas 7 to 15 per cent.

In this investigation the values of the standard curve were based on several incubations from different days. With this mean standard curve a good correlation between dilution and lysis areas was obtained and variations in slope were avoided. The reliability of the standard curve was then checked every day.

The fibrinolytic activity studied by the present method is partly a measure of the amount of vessels in the nasal mucosa and partly a measure of the amount of plasminogen activators in the vessels.

Only small pieces of nasal mucosa (3 to 5 mg) are required for the analyses. At different occasions at least four to six biopsies can be taken from the same individual by means of a Hartman ear polyp forceps. By using these forceps about the same amount of tissue can be taken each time. The biopsies must be taken apart from each other to avoid biopsies with scar tissue.

When eight different parts of the nasal mucosa from one inferior concha were analysed there was a fairly good correlation between the lysis areas corresponding to 0.10 mg nitrogren per ml nasal mucosa extract (variation coefficient five per cent).

This shows that it probably is of minor importance from what part of the concha the biopsy is taken. The amount of activator is obviously equally distributed in these parts of the nasal mucosa. It is thus possible to compare the fibrinolytic activities in biopsies taken at different occasions from the same individual.

the nose than in younger patients (chapter 4 B). It was also more common with distinct arterial bleedings in older patients (chapter 4 B). These bleedings are more difficult to arrest and they might be an explanation to the higher frequency observed.

In the population sample 10 per cent of the subjects had noted an association between epistaxis and stress/fatigue. We have as yet no information to explain in what way stress is correlated to epistaxis.

Conclusions

Epistaxis is a common symptom. In a population sample 60 per cent of the subjects had had epistaxis at least once in life but only one subject of ten, who had had epistaxis, had been treated for it by a doctor.

Subjects who frequently have nose bleedings do not necessarily require professional therapy.

The incidence of epistaxis per year is at least 15 per cent for men and 9 per cent for women.

B. Subjective explanation of the start of nose bleeding, localisation of the bleeding source and the effect of different local treatments

All 1118 registered patients (chapter 2) were asked if they could themselves give any possible explanation to the start of the nose bleeding (chapter 3 A question number 10). The answers which were given are presented.

After the clinical examination of the registered patients the localisation of the bleeding source and the kind of bleeding were classified (chapter 3 B). The results of these classifications are presented together with the results of the local therapy (chapter 3 C).

Results

Subjective explanation of the start of nose bleeding. The nose bleedings started without any obvious reason (when lying in bed, sitting on a chair, washing hands, eating etcetera) in 65 per cent of all patients. The other patients could themselves give possible explanations to the release of the nose bleeding.

Different traumas to the structures of the nasal cavities were primary releasing factors in 28.5 per cent of the patients (table 16).

Physical exhaustion before the release of the nose bleeding was given as explanation by 5 per cent of the patients (for example after lifting heavy things, in connection with sports, after digging).

Psychical exhaustion before and in connection with the start of the nose bleeding was mentioned as explanation by 1.5 per cent of the patients (for example when preparing examinations, work in stress, personal anxieties and sorrows).

In 62 of 111 hospitalized patients the bleeding started without any obvious reason. About one third (20/62) said that the bleeding started between 7 and 9 o'clock in the morning.

Localisation of the bleeding source. The localisation of the bleeding source was somewhat different in different ages. In patients less than 20 years old 91 per cent bled from the nasal septum. Patients more than 40 years old had bleedings from the nasal septum in 88 per cent (table 17).

The bleeding source was invisible in 5 per cent

attending an ENT doctor for epistaxis. In the same way it was also possible to calculate the frequency of subjects being hospitalized due to epistaxis. As shown in table 15 both these frequencies were higher in inhabitants more than 60 years old than in inhabitants less than 60 years old.

Epistaxis associated with stress. According to the answers in the questionnaire a association between stress/fatigue and epistaxis was noted by 40 subjects (10 %) in the population sample 9 of these subjects were habitual bleeders.

Comments

The incidence of epistaxis in a population sample has only been reported by Weiss (1972), who noted that 7 to 14 per cent of the subjects had had epistaxis at least once In this study it was observed that 60 per cent of the subjects in the population sample had had epistaxis at least once in life

Single or several bleedings from the nose every year was observed in 15 per cent of the man and 9 per cent of the women in the population sample. Probably the incidence of epistaxis per year in the population is above the mentioned values, as subjects with a single bleeding during the last year were not registered.

Habitual bleeders were found less frequently in hospitalized patients than in out patients, which shows that there is no strong correlation between habitual bleeding and the severity of nose bleeding.

The occurrence of epistaxis was shown to be poorly correlated to the requirement of treatment by a doctor In the population sample 60 per cent of the subjects had had epistaxis at least once but only 6 per cent of the subjects had been treated for epistaxis by a doctor

The frequency of subjects attending an ENT doctor due to epistaxis was higher per 10.000 inhabitants and year in inhabitants more than 60 years old than in inhabitants less than 60 years old. The bleeding source in older patients was more frequently localized in the posterior parts of

Table 19. Local treatments of epistaxis. During 1 1/2 years 1 118 patients were treated for epistaxis in Göteborg. The primary treatment was successful in 1 003 patients, they had no new bleeding that required new treatment within 24 hours. In 115 patients (10 %) the primary treatment was unsuccessful, they had to be treated a second time. The therapy used is listed below

	Primary treatment No therapy	Cauterization with cromic acid	Electrical cauterisation	Spongostan® and Cyklokapron®	Anterior gauze tampons	Posterior Foley and anterior gauze tampons

kapron® (compare chapter 4 H to 4 L) or posterior Foley catheter together with anterior gauze tampons soaked with Cyklokapron® as shown in figure 13.

C. Frequency of upper respiratory infections and intake of acetylsalicylic acid

The frequency of histories of upper respiratory infections and intake of acetylsalicylic acid the week before the epistaxis started were studied in the patients and compared with the frequency in the population sample. The subjects in the population sample were asked whether they had noted an association between upper respiratory infections and epistaxis.

Study groups. The following groups were studied: Population sample, out patients and hospitalized patients (chapter 2).

Methods. The answers to questions numbers 3, 4, 7 and 8 in the questionnaire (chapter 3 A) were used for statistical analyses. The distribution of age and sex was different in the population sample and the patient groups. Therefore a division of the study groups into homogenous subgroups with regard to sex and age was performed in order to eliminate the influence of sex and age in the correlations. The occurrences of upper respiratory infections and intake of acetylsalicylic acid in the subgroups of the population sample were correlated to the occurrences in the subgroups of the patients by using contingency tables. The contingency tables from the subgroups were then pooled by a special technique (Odeh and Wede) 1974) to get a general conclusion about the correlations in the study groups.

A difference is regarded as significant when $p < 0.01$

Results

In the population sample 30 *per cent of the* subjects had had an upper respiratory infection during the previous week compared with 49 per cent in the out patients and 54 per cent in the hospitalized patients (figure 14, appendix 1). In all age groups the difference was statistically significant between the subjects in the population sample and the patients.

In the population sample 32 per cent of the subjects had taken acetylsalicylic acid during the previous week. The corresponding frequency in the out patients was 51 per cent and the hospitalized patients 68 per cent. The difference was *statistically significant* in all age groups between the subjects in the population sample and the patients (figure 14, appendix 1).

It was more common that the patients than the

Table 17 Localisation of the bleeding source

	Per cent of patients in the age group			
	<20	20–39	≥40 years	Total
Kiesselbach area	82	59	47	57

Lateral parts, floor of the nose	4	10	15	1
Bleeding source not visiable	5	14	17	14

of the patients less than 20 years old and in 17 per cent of the patients more than 40 years old.

In 1.5 per cent (15/1118) of the patients bleeding sources were observed in both nasal cavities.

Kind of bleeding. In 32 per cent of the patients it was impossible to estimate what kind of bleedings the patients suffered from either the bleeding source was not visible or the bleeding too severe. There was no difference between the age groups in this respect (table 18).

In 11 per cent of the patients the nose bleeding had stopped when the patients were examined.

In the ages less than 40 years distinct venous bleedings were more than three times as frequent as distinct arterial bleedings. In patients more than 40 years of age the latter were about as frequent as distinct venous bleedings.

The effect of different local treatments. No therapy was given in 6 per cent of the patients (Table 19). In 68 per cent of the patients the epistaxis was primarily treated with cromic acid cauterisation.

Spongostan® soaked with Cyklokspron® was used instead of anterior gauze tampons in 14 per cent of the patients. The therapy was primarily good in 78 per cent of the treated patients. It was however impossible to arrest severe bleedings which had to be treated with tampons.

Anterior gauze tampons primarily arrested the bleeding in 84 per cent of the treated patients. The unsuccesful cases were treated with posterior Foley catheter and anterior gauze tampons. The nasal mucosa in many cases showed macroscopic signs of inflammatory reaction after the gauze tampon had been taken away finally. This was not observed when Spongostan® soaked with Cyklokapron® was used.

Posterior Foley catheter and anterior gauze tampons primarily arrested the nose bleeding in all cases but one. This therapy was uncomfortable for the patients and required hospitalisation.

Conclusions

The nose bleeding started without any obvious reason when resting in 65 per cent of the patients. In 28.5 per cent of the patients the bleeding was released by different traumas against the structures of the nasal cavities.

The bleeding source was localized on the nasal septum in 91 per cent of the patients less than 20 years old and in 68 per cent of the patients more than 40 years old.

Distinct arterial bleedings were more frequent in patients more than 40 years old than in patients less than 40 years old.

With the therapeutic principles used it was possible to arrest all nasal bleedings. As local therapy of epistaxis is recommended cromic acid cauterisation, Spongostan® soaked with Cyklokapron® anterior gauze tampons soaked with Cyklo-

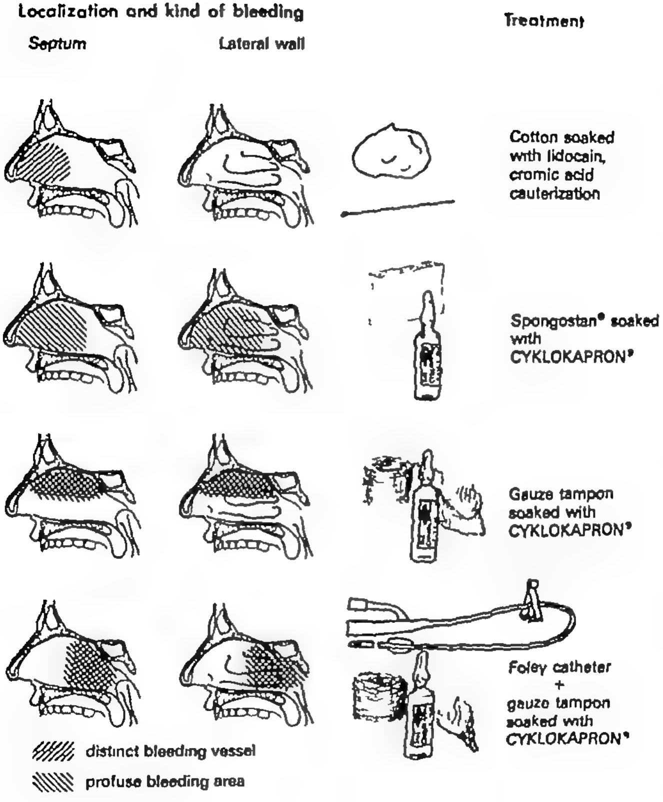

Figure 13 Local therapy recommended in patients with epistaxis.

All examined pieces of nasal mucosa included the superficial parts of the mucous membrane with mucous and serous glands.

The intensity of the inflammatory reaction was classified in four groups. 0 = no inflammatory reaction. + = slight inflammatory reaction with a few leucocytes demonstrable in the epithelium and lamina propria. ++ = moderate inflammatory reaction. Several leucocytes as well as lymphocytes and plasma cells were seen in the epithelium, lamina propria and seromucinous glands. On the surface an exudate of cell detritus and inflammatory cells was observed. +++ = severe inflammatory reaction. A lot of inflammatory cells were seen in the epithelium, lamina propria and seromucinous glands. The epithelium was transformed to stratified squamous epithelium. Cell detritus and inflammatory cells were also observed on the surface of the mucosa.

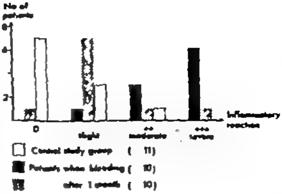

Figure 15. Signs of inflammatory reactions in nasal mucosa biopsies from patients with epistaxis and controls.

Results

Histology of the nasal mucosa in the control group

In seven subjects no signs were seen of inflammatory reactions (figure 15). The mucous membrane was covered by columnar ciliated epithelium with goblet cells (figure 16). In older subjects the columnar epithelium was sometimes replaced by a stratified squamous epithelium. The lamina propria contained mucous and serous glands together with a lot of thin walled small vessels. In the lamina propria occasional inflammatory cells such as lymphocytes and plasma cells were frequently observed.

cylic acid among those who had not had an upper respiratory infection. There was also a significant difference in the pooled age groups between the population sample and the patient groups with regard to upper respiratory infections among those who had not taken acetylsalicylic acid

In the population sample 43 subjects (10 %) had noted an association between upper respiratory infections and epistaxis, 12 of these subjects were habitual bleeders.

Comments

During four weeks in the winter when the incidence of upper respiratory infections is known to be high the subjects in the population sample were asked whether they had had an upper respiratory infection and whether they had taken acetylsalicylic acid. If the subjects had been asked throughout the whole year the incidence of upper respiratory infections probably would have been less in the population sample In spite of this the incidence of upper respiratory infections, the week before the question was asked was significantly higher in all age groups of the patients than in all age groups of the population sample.

The results are in accordance with the postulation that histories of upper respiratory infections and intake of acetylsalicylic acid separately might predispose to occasional epistaxis. This is concluded becauce the incidences of upper respiratory infections and intake of acetylsalicylic acid were higher in the patient groups than in the population sample even when patients and subjects were compared within subgroups.

An inflammatory reaction caused by an infection in the nose probably gives a vulnerable mucosa and changes in the vessel walls, which might rupture and start the nose bleeding (compare chapter 1 E and 4 D). Acetylsalicylic acid interfere with the platelet function (Cronberg et al 1970) gives a prolonged bleeding time (Mielke et al 1968 compare chapter 4 G) an impaired primary hemostasis. Even a primary small bleeding might in this way be of clinical importance.

Conclusions

Histories of upper respiratory infections and intake of acetylsalicylic acid were more common in patients with epistaxis than in subjects in the population sample

Subjects in the population sample who had bled the previous week had had an upper respiratory infection during which they consumed acetylsalicylic acid, in a significantly higher frequency than the other subjects in the population sample.

About 10 per cent of the subjects in the population sample had noted an association between upper respiratory infections and nose bleedings.

Together and probably also separately an upper respiratory infection and intake of acetylsalicylic acid might be predisposing to occasional epistaxis.

D Microscopic picture of the nasal mucosa

The aim of this study was to investigate whether any inflammatory reactions could be observed in biopsies taken from the nasal mucosa in patients with epistaxis and to compare the findings in the patients with the findings in the subjects in a control group.

Study groups. Biopsies from the nasal mucosa were taken from 11 randomly selected patients with epistaxis. Five of the patients had bled less than 3 hours, three patients had bled repeatedly more than 7 days. (table 20)

The control groups consisted of 11 healthy subjects (medical assistants or relatives to them) with the same sex and about the same age as the patients. None of the subjects had had an upper respiratory infection the week before the examination.

Methods. All biopsies were taken with an ear polyp forceps (Hartmann) without anestesia. Two biopsies were taken from each patient When the patient bled the first biopsy was taken from the anterior part of the inferior concha on the side opposite to the bleeding. The second biopsy was taken one month later some mm apart from the first

From the subjects in the control group only one biopsy was taken from the anterior part of the inferior concha.

The excised piece of nasal mucosa was immediately fixed in 10 per cent neutral formalin The mucosa was embedded in paraffin and sections 3 micron thick, were stained according to Weigerts modification of van Giesen's haematoxylin method. Some sections were stained with haematoxylin and eosin.

All examined pieces of nasal mucosa included the superficial parts of the mucous membrane with mucous and serous glands.

The intensity of the inflammatory reaction was classified in four groups. 0 = no inflammatory reaction. + = slight inflammatory reaction with a few leucocytes demonstrable in the epithelium and lamina propria. ++ = moderate inflammatory reaction. Several leucocytes as well as lymphocytes and plasma cells were seen in the epithelium, lamina propria and seromucinous glands. On the surface an exudate of cell detritus and inflammatory cells was observed. +++ = severe inflammatory reaction. A lot of inflammatory cells were seen in the epithelium, lamina propria and seromucinous glands. The epithelium was transformed to stratified squamous epithelium. Cell detritus and inflammatory cells were also observed on the surface of the mucosa.

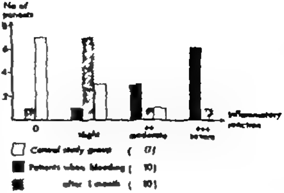

Figure 15. Signs of inflammatory reactions in nasal mucosa biopsies from patients with epistaxis and controls.

Results

Histology of the nasal mucosa in the control group

In seven subjects no signs were seen of inflammatory reactions (figure 15). The mucous membrane was covered by columnar ciliated epithelium with goblet cells (figure 16). In older subjects the columnar epithelium was sometimes replaced by a stratified squamous epithelium. The lamina propria contained mucous and serous glands together with a lot of thin walled small vessels. In the lamina propria occasional inflammatory cells such as lymphocytes and plasma cells were frequently observed.

URI upper respiratory infection
ASA acetylsalicylic acid

the classification of the inflammatory reactions was performed by ass. prof Göran Hansson, Göteborg.

In three subjects a slight and in one subject a moderate inflammatory reaction was observed

*Histology of the nasal mucosa in patients with epistaxis** In all biopsies from the bleeding patients signs of inflammatory reactions were seen in the nasal mucosa (figure 15 table 20) In six of the biopsies the reactions were severe (figure 17) and in three they were moderate

The biopsies that were taken one month after the bleeding also showed inflammatory cells in the mucosa but the inflammatory reaction was less pronounced that one month before

Table 20 shows the duration of epistaxis before the biopsies were taken, the result of bacteriological isolation and the leucocyte count. As seen six patients had had an upper respiratory infection the week before the bleeding started three patients had growth of potentially pathological bacterial strains in the nose (staphylococcus aureus and hemophilus influenzae) and two patients had leucocyte count over the reference value 9 000/ mikroliter

Comments

In all patients with epistaxis inflammatory reactions were seen in the nasal mucosa biopsies, taken from the side opposite to the bleeding side Five of the patients had only bled during one to two hours and it is doubtful that a nose bleeding in the other nasal cavity during this short time should give an inflammatory reaction of the observed magnitude in the examined nasal cavity

Most patients had a leucocyte count within the reference value The increased number of leucocytes observed in the nasal mucosa biopsies was thus not refound in the blood.

In only three patients potentially pathological bacterial strains were isolated in the nose Thus the inflammatory reaction in the nasal biopsies can not in most cases be explained by localized bacterial infections.

Conclusion

It is obvious that patients with epistaxis have inflammatory reactions in the nasal mucosa when they bleed and that these reactions probably are not caused by but a cause of the nose bleeding, indicating that a damaged mucosa is more vulnerable

* the classification of the inflammatory reactions was performed by ass prof Goran Ha son Göteborg

In some patients the inflammatory reactions observed might be due to upper respiratory infections.

E. Frequency of histories of hypertension

In order to investigate whether hypertension was associated with nose bleedings or not the frequency of histories of hypertension in patients with epistaxis was compared with the frequency in the population sample

In a study of 5 223 patients with hypertension was shown that only 50 per cent of the patients knew that they had hypertension. (Wilhelmsen 1973). It is thus very possible that the frequency of hypertension in this study is greater than the frequency of histories indicates.

As it is an established truth that hypertension gives nose bleedings one might postulate that all patients with epistaxis who knew that they had hypertension would report it In this way the frequency of reported histories of hypertension might be higher in the patient groups than in the population sample

Study groups. The following groups were studied population sample out patients and hospitalized patients (chapter 7)

Methods The answers to questions numbers 1 2 3 4 and 7 in the questionnaire (chapter 3 A) were used for statistical analyses

The subjects in the population sample and the patients with a *history of hypertension* were subdivided into age groups in order to avoid the influence of sex and age in the analysis. The frequency of histories of hypertension in the subgroups of the population sample was correlated to the frequency in the subgroups of the patients by using contingency tables The contingency tables were then pooled as described in chapter 4 C

Results

Occasional nose bleedings. When the different age groups were pooled there was no statistical difference in the frequency of histories of hypertension between the out patients and the subjects in the population sample ($p = 0.31$)

The analysis indicated instead that it was somewhat more common with histories of hypertension in the population sample than in the

Figure 16. Microscopic picture of nasal mucosa without signs of inflammatory reactions. 192.

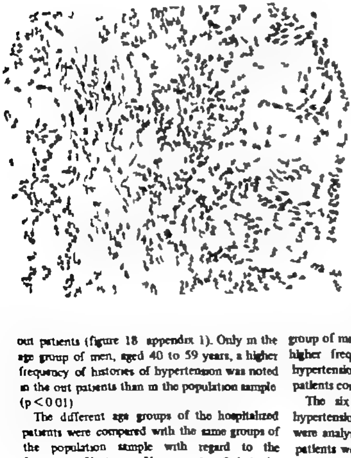

Figure 17. Microscopic picture of nasal mucosa with signs of severe inflammatory reaction. 192.

out patients (figure 18 appendix 1). Only in the age group of men, aged 40 to 59 years, a higher frequency of histories of hypertension was noted in the out patients than in the population sample ($p < 0.01$).

The different age groups of the hospitalized patients were compared with the same groups of the population sample with regard to the frequency of histories of hypertension. Only in the group of men, aged 40 to 59 years, a significantly higher frequency ($p = 0.04$) of histories of hypertension was noted in the hospitalized patients compared with the population sample.

The six hospitalized men with histories of hypertension, in the age group 40 to 59 years, were analysed separately. It was found that three patients were alcoholics and had elevated transaminase values (chapter 4 G), one patient was an

In three subjects a slight and in one subject a moderate inflammatory reaction was observed

*Histology of the nasal mucosa in patients with epistaxis** In all biopsies from the bleeding patients signs of inflammatory reactions were seen in the nasal mucosa (figure 15 table 20) In six of the biopsies the reactions were severe (figure 17) and in three they were moderate

The biopsies that were taken one month after the bleeding also showed inflammatory cells in the mucosa but the inflammatory reaction was less pronounced that one month before.

Table 20 shows the duration of epistaxis before the biopsies were taken the result of bacteriological isolation and the leucocyte count. As seen, six patients had had an upper respiratory infection the week before the bleeding started three patients had growth of potentially pathological bacterial strains in the nose (staphylococcus aureus and hemophilus influenzae) and two patients had leucocyte count over the reference value 9 000/ mikroliter

Comments

In all patients with epistaxis inflammatory reactions were seen in the nasal mucosa biopsies, taken from the side opposite to the bleeding side Five of the patients had only bled during one to two hours and it is doubtful that a nose bleeding in the other nasal cavity during this short time should give an inflammatory reaction of the observed magnitude in the examined nasal cavity

Most patients had a leucocyte count within the reference value The increased number of leucocytes observed in the nasal mucosa biopsies was thus not refound in the blood.

In only three patients potentially pathological bacterial strains were isolated in the nose Thus the inflammatory reaction in the nasal biopsies can not in most cases be explained by localized bacterial infections.

Conclusion

It is obvious that patients with epistaxis have inflammatory reactions in the nasal mucosa when they bleed and that these reactions probably are not caused by but a cause of the nose bleeding, indicating that a damaged mucosa is more vulnerable In some patients the inflammatory reactions observed might be due to upper respiratory infections.

E. Frequency of histories of hypertension

In order to investigate whether hypertension was associated with nose bleedings or not the *frequency of histories of hypertension in patients* with epistaxis was compared with the frequency in the population sample

In a study of 5.223 patients with hypertension was shown that only 50 per cent of the patients knew that they had hypertension. (Wilhelmsen 1973). It is thus very possible that the frequency of hypertension in this study is greater than the frequency of histories indicates.

As it is "an established truth" that hypertension gives nose bleedings one might postulate that all patients with epistaxis who knew that they had hypertension would report it In this way the frequency of reported histories of hypertension might be higher in the patient groups than in the population sample

Study groups. The following groups were studied population sample out patients and hospitalized patients (chapter 2)

Methods The answers to questions numbers 1 2 3 4 and 7 in the questionnaire (chapter 3 A) were used for statistical analyses.

The subjects in the population sample and the patients *with a history of hypertension* were subdivided into age groups in order to avoid the influence of sex and age in the analysis. The frequency of histories of hypertension in the subgroups of the population sample was correlated *to the frequency in the subgroups of the patients* by using contingency tables The contingency tables were then pooled as described in chapter 4 C.

Results

Occasional nose bleedings. When the different age groups were pooled there was no statistical difference in the frequency of histories of hypertension between the out patients and the subjects in the population sample ($p = 0.31$)

The analysis indicated instead that it was somewhat more common with histories of hypertension in the population sample than in the

* the classification of the inflammatory reactions was performed by prof Goran Hansson, Göteborg.

alcoholic with transaminase values within the reference values, one patient had elevated transaminase values but was not an alcoholic and one patient had thrombocytopenia and impaired blood coagulation.

Patients and subjects in the population sample with histories of hypertension had taken acetylsalicylic acid without having an upper respiratory infection in a higher frequency ($p < 0.05$) than those with no histories of hypertension (figure 19).

The frequency of patients with hypertension who were treated with drugs was equal in the hospitalized patients and in the population sample (figure 19).

In patients more than 40 years old it was noted that 21 per cent (37/175) of the patients with a history of hypertension had distinct arterial bleeding. In the same age group 19 per cent (99/514) of the patients without a history of hypertension had distinct arterial bleeding. The difference is not significant.

Habitual bleedings. In the population sample no habitual bleeder was found among 62 subjects with a history of hypertension (figure 19).

Among 148 out patients with a history of hypertension 21 habitual bleeders were observed. No systematical research for other possible predisposing diseases or conditions were performed during the registration of the out patients. Spontaneous notations of such diseases or conditions as dicumarolitherapy, inherited thrombocytopenia, *Morbus Osler*, papilloma nasi, anterior septal perforations were however made by the examining doctor in 8 of these habitual bleeders. The frequency of habitual bleeders was higher in out patients without a history of hypertension than in those with the latter.

Among 32 hospitalized patients with a history of hypertension were found 2 habitual bleeders, one of these patients had a family history of epistaxis and the other was a chronic alcoholic with severe abnormal transaminase values.

Comments

Hypertension is often mentioned as an etiological factor of epistaxis (compare chapter 1 B). In investigations of Shaheen (1970) and Weiss (1972) no association between epistaxis and hypertension was observed.

When the possible association between histories of hypertension and epistaxis was investigated in this clinical study difficulties in evaluating predisposing factors became obvious. As mentioned in chapter 4 C histories of upper respiratory infections and intake of acetylsalicylic acid might be predisposing to occasional nose bleeding.

Irrespective of a difference in frequency of histories of upper respiratory infection and intake of acetylsalicylic acid, a lower frequency of histories of hypertension was found in the out patients than in the population sample.

A significantly higher frequency of histories of hypertension was only observed in male patients between 40 and 59 years compared with the population sample.

Other diseases than upper respiratory infections might interfere with the statistical analyses in this age group. It was noted that four out of six of the hospitalized men in this group were alcoholics. The frequency of alcoholics in the population sample and the out patients is unknown and it is thus impossible to estimate to what extent the difference in frequency of histories of hypertension between the population sample and the patients was a difference in frequency of alcoholics.

Distinct arterial bleedings were not more common in patients with a history of hypertension than in the other patients. This indicates that a history of hypertension does not separately increase the risk of getting a visible arterial bleeding.

When patients with other possible explanations of habitual bleedings were excluded it was found that no subject in the population sample, no hospitalized patient and 13 out patients with histories of hypertension were habitual bleeders. It was also noted that habitual bleedings were less frequent in patients and subjects with a history of hypertension than in patients and subjects without. A history of hypertension did not seem to predispose to habitual nose bleedings.

Conclusion

The results of the statistical analyses indicate that a history of hypertension probably is not related to nose bleedings.

Comments

Hypertension is often mentioned as an etiological factor of epistaxis (compare chapter 1 B). In investigations of Shaheen (1970) and Weiss (1972) no association between epistaxis and hypertension was observed.

When the possible association between histories of hypertension and epistaxis was investigated in this clinical study difficulties in evaluating predisposing factors became obvious. As mentioned in chapter 4 C histories of upper respiratory infections and intake of acetylsalicylic acid might be predisposing to occasional nose bleeding.

Irrespective of a difference in frequency of histories of upper respiratory infection and intake of acetylsalicylic acid, a lower frequency of histories of hypertension was found in the out patients than in the population sample.

A significantly higher frequency of histories of hypertension was only observed in male patients between 40 and 59 years compared with the population sample.

Other diseases than upper respiratory infections might interfere with the statistical analyses in this age group. It was noted that four out of six of the hospitalized men in this group were alcoholics. The frequency of alcoholics in the population sample and the out patients is unknown and it is thus impossible to estimate to what extent the difference in frequency of histories of hypertension between the population sample and the patients was a difference in frequency of alcoholics.

Distinct arterial bleedings were not more common in patients with a history of hypertension than in the other patients. This indicates that a history of hypertension does not separately increase the risk of getting a visible arterial bleeding.

When patients with other possible explanations of habitual bleedings were excluded it was found that no subject in the population sample, no hospitalized patient and 13 out patients with histories of hypertension were habitual bleeders. It was also noted that habitual bleedings were less frequent in patients and subjects with a history of hypertension than in patients and subjects without. A history of hypertension did not seem to predispose to habitual nose bleedings.

Conclusion

The results of the statistical analyses indicate that a history of hypertension probably is not related to nose bleedings.

F Registrated blood pressures

The blood pressure values of patients who had had epistaxis were compared with the values of a control group in order to study whether there was any difference between the patients and the controls.

Study groups. The following groups were studied 1 Extensively examined patients (chapter 2) 2. A population sample from Bergen Before this investigation started it was deceided to use a population sample containing 23 794 inhabitants of Bergen Norway (Boe 1957) as a reference group

Methods. The blood pressure was measure as described in chapter 3 D

As the Bergen population sample consisted of many subjects it was possible to calculate the mean and standard deviation of the blood pressure in age classes with five years interval In the present investigation such a grouping was impossible to use as each group then would contain only a few patients In order to test statistically whether there was any difference in blood pressure between the Bergen population sample and the present patients, it was decided to use sign tests The mean values of blood pressure in the different age groups in the Bergen population sample were connected and the blood pressures of the patients were then plotted and compared with these mean value lines.

Results

No significant differences in blood pressure were noted between the patients and the Bergen population sample tested with sign tests (figure 20 and 21)

The mean values and the standard deviations in different age groups of the patients are presented in figure 22 and 23 together with the mean values and standard deviations in some age groups of the Bergen population sample

Comments

According to Boe (1957) it is inwise to compare the results from blood pressure registrations in different study groups as the blood pressure might be taken during different conditions When this investigation started precautions were taken to measure the blood pressure in the patients in the same way as in the Bergen population sample There might however be slight differences between the measurements all the same

In the present study the blood pressure of the patients were measured some weeks after the actual bleeding. It is known that extensive bleedings cause a drop in blood pressure due to decreased blood volume It is, however unlikely that the blood volume should be decreased some weeks after the actual bleeding, and in this way cause a lower blood pressure than normally

By using the described test model the definition problem of hypertension is avoided As shown in figure 20 and 21 there was no significant difference in systolic and diastolic blood pressure between the patients and the Bergen population sample

Conclusion

The distribution of different blood pressures was the same in the examined patients who had had epistaxis as in a population sample

G Clinical observations and laboratory data in 155 extensively examined patients

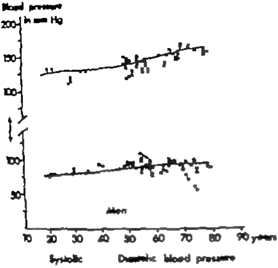
The patients who were studies in this chapter are presented in chapter 2 The methods which were used are described in chapter 3 A F G H The statistical analyses were performed with contingency tables.

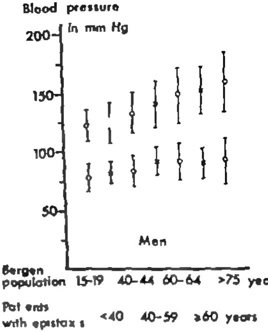
Clinical observation

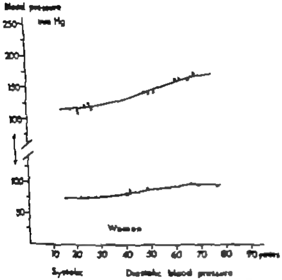
Family history of epistaxis. In the study group 41 patients (26 %) had near relatives (parents children brothers or sisters) who used to bleed from the nose frequently Ten of the patients had more than two relatives with a history of frequent nose bleedings. There was a significantly higher frequency ($p < 0.02$) of habitual bleeders among the patients with family history of epistaxis than among the other patients.

No difference was observed in the frequency of abnormal values of routine tests of hemostasis between patients with family history of epistaxis and patients without (table 21)

History of bleeding tendency All patients were asked if they used to get hematomas on the arms or on the body without traumas and if they used to bleed for a long time after a tooth extraction or after slight skin cuts. An affirmative answer to one







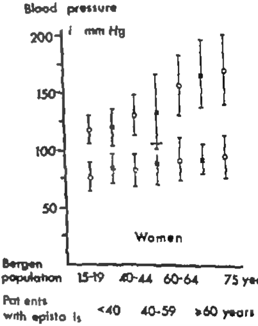


Figure 20 and 21. The blood pressures of the patients in the present study are plotted according to age. Solid lines indicate mean values of blood pressure in the Bergen population.

Figure 22 and 23. Mean values and standard deviations of systolic and diastolic blood pressure in different ag groups of patients with epistaxis ( ) and in some ag groups of the Bergen population (o—).

or more of these questions was given by 28 patients (18 ‑c)

The frequency of abnormality in one or more of the routine tests of hemostasis was 57 per cent in patients with a history of bleeding tendency and 38 per cent in patients without The difference was not significant. Five patients with a history of bleeding tendency were habitual bleeders (table 21)

Habitual bleeding In the studied group 17 patients (11 %) used to bleed several times every year The frequency of abnormality in one or more of the routine tests of hemostasis was 41 per cent in the habitual bleeders and thus the same as the group in all (table 21)

Other diagnosed diseases. The number of patients with diagnosed diseases known by the patient or discovered at the examination are presented in table 22

Alcoholism. All patients were asked if they had been hospitalized any time on account of abuse of alcohol. An affirmative answer was given by 22 patients. A strong smell of alcohol was found in 10 of these patients when they were examined Further 4 patients had a strong smell of alcohol but denied hospitalisation on account of abuse of alcohol They admitted however that they were "moderate to severe" drinkers. In all 26 patients (17 %) were assumed to be alcoholics.

Only two of the alcoholics were women, they were more than 60 years old The largest group of alcoholics were 16 men observed in the age group between 40 and 59 years old containing 39 men.

Abnormality in one or more of the blood clotting tests were found in 3 alcoholics. Two of the alcoholics were habitual bleeders (table 21).

Laboratory data

Leucocyte count (LC) C-reactive protein (CRP) erythrocyte sedimentation rate (ESR) antistreptolysine titer (AST) and antistaphylolysine titer (ASTA). When the study was planned it was decided to try to separate viral upper respiratory infections from potent acute bacterial upper respiratory infections. The reason for this separation was the assumption that more pronounced injuries to the nasal mucosa would be caused by potent acute bacterial infections than by viral infections. The macroscopic appearance of the nasal mucosa was regarded as unsuitable for this separation

Patients in whom a potent acute bacterial infection could be diagnosed for certain were patients with an acute sinusitis diagnosed by puncture By use of the unspecific tests LC CRP and ESR together with the specific tests AST and ASTA attempts were made to get a basis for the differentiation between viral and potent acute bacterial upper respiratory infections.

Laboratory signs of a potent acute bacterial infection were found in 32 patients (21 %) as shown in table 23 Among 75 patients with a history of an upper respiratory infection 22 patients (29 %) had laboratory signs of a potent

* the number of patients with defects in the hemostasis is presented page 48

Table 23. Number of patients with laboratory signs of potent acute bacterial infection. A patient was regarded to have laboratory signs of potent acute bacterial infection if one or more of the following conditions were fulfilled.

1. Leucocyte count (LC) more than 13 000/microliter in the first blood sampling and less than 9 000/microliter in the second sampling.
2. C-reactive protein (CPR) more than 10 µg/ml in the first blood sampling and a decrease of more than 50 per cent in the second blood sampling.
3. Erythrocyte sedimentation rate (ESR) more than 30 mm/hr in men or 38 mm/hr in women in the first blood sampling and a decrease of more than 50 per cent in the second blood sampling.
4. A difference of two titer steps or more in antistreptolysine titer (AST) between the two examinations.
5. A difference of two titer steps or more in antistaphylolysine titer (ASTA) between the two examinations.

	Total	Number of patients with laboratory signs of LC	CPR	ESR	AST	ASTA	at least one sign
Patients with							
No history of upper respiratory infection	80	1	7	0	2	0	10 (13 %)
History of upper respiratory infection	75	4	16	6	2	0	22 (29 %)
Diagnosed acute sinusitis	10	1	3	0	0	0	4 (40 %)

acute bacterial infection. It must, however, be stressed that only four of the ten patients with a diagnosed acute sinusitis had laboratory signs of a potent acute bacterial infection.

Among the remaining 80 patients, who had not had any upper respiratory infection the week before they came to the hospital, were found 10 patients (13 %) with laboratory signs of a potent acute bacterial infection. No search was carried out to localize the infections in these ten patients.

None of the examined patients with leucocyte count values above the reference value had leucemia.

Creatinine in serum. None of the patients were uremic. In 12 patients (8 %) the kidney function appeared to be impaired, the creatinine concentration being above the reference value but less than 1.8 mg/100 ml.

Transaminases in serum. In 40 patients (26 %) the values of aspartate aminotransferase (GOT)

or more of these questions was given by 28 patients (18 %)

The frequency of abnormality in one or more of the routine tests of hemostasis was 57 per cent in patients with a history of bleeding tendency and 38 per cent in patients without The difference was not significant. Five patients with a history of bleeding tendency were habitual bleeders (table 21)

Habitual bleeding In the studied group 17 patients (11 %) used to bleed several times every year The frequency of abnormality in one or more of the routine tests of hemostasis was 41 per cent in the habitual bleeders and thus the same as the group in all (table 21)

Other diagnosed diseases. The number of patients with diagnosed diseases, known by the patient or discovered at the examination are presented in table 22.

Alcoholism. All patients were asked if they had been hospitalized any time on account of abuse of alcohol. An affirmative answer was given by 22 patients. A strong smell of alcohol was found in 10 of these patients when they were examined Further 4 patients had a strong smell of alcohol but denied hospitalisation on account of abuse of alcohol They admitted however that they were "moderate to severe drinkers. In all 26 patients (17 %) were assumed to be alcoholics

Only two of the alcoholics were women they were more than 60 years old The largest group of alcoholics were 16 men observed in the age group between 40 and 59 years old containing 39 men.

Abnormality in one or more of the blood clotting tests were found in 3 alcoholics Two of the alcoholics were habitual bleeders (table 21)

Laboratory data

Leucocyte count (LC) C-reactive protein (CRP) erythrocyte sedimentation rate (ESR) antistreptolysine titer (AST) and antistaphylolysine titer (ASTA). When the study was planned it was decided to try to separate viral upper respiratory infections from potent acute bacterial upper respiratory infections. The reason for this separation was the assumption that more pronounced injuries to the nasal mucosa would be caused by potent acute bacterial infections than by viral infections. The macroscopic appearance of the nasal mucosa was regarded as unsuitable for this separation

Patients in whom a potent acute bacterial infection could be diagnosed for certain were patients with an acute sinusitis diagnosed by puncture By use of the unspecific tests LC CRP and ESR together with the specific tests AST and ASTA attempts were made to get a basis for the differentiation between viral and potent acute bacterial upper respiratory infections.

Laboratory signs of a potent acute bacterial infection were found in 32 patients (21 %) as shown in table 23 Among 75 patients with a history of an upper respiratory infection 22 patients (29 %) had laboratory signs of a potent

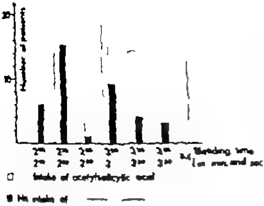

Figure 24 Bleeding time (Duke) in patients without thrombocytopenia with regard to intake of acetylsalicylic acid the previous week.

sured in all patients on at least three occasions. The values measured at the first examination and the values which were measured 2 to 4 days after the bleeding was finally arrested are presented in figure 25 to 28.

When the hemoglobin value which was measured 2 to 4 days after the bleeding was finally stopped, was below the reference value the patient was assumed to have anemia. It was found that 43 per cent of the out patients and 73 per cent of the hospitalized patients had a hemoglobin value below the reference value indicating that they were anemic.

The decrease in hemoglobin concentration between the first blood sampling and the blood sampling 2 to 4 days after the bleeding was finally arrested was 1.3±1.3 g/100 ml in the hospitalized patients and 0.7±0.7 g/100 ml in the out patients.

The number of reticulocytes were counted in all patients on at least three occasions. The values measured at the first examination and the values which were measured 4 to 8 days after the bleeding was finally stopped are presented in figure 29 to 32.

Mean values and standard deviation of the reticulocyte count values which were measured 4 to 8 days after the bleeding was finally arrested were in the hospitalized patients 28±16 and in the out patients 22±14 reticulocytes per 1000 counted erythrocytes. It was found that only 2 patients (1.5 %) had reticulocyte count values within the reference value.

There was no statistically significant difference between patients with hemoglobin values less than 10 g/100 ml and the other patients with respect to family history of epistaxis, history of bleeding tendency, habitual bleeding, histories of upper respiratory infections, intake of acetylsalicylic acid or hypertension. Neither was there found any higher frequency of patients with hemoglobin values less than 10 g/100 ml in patients with elevated values of creatinine in serum, abnormal transaminase values or abnormal values of routine tests of hemostasis.

Blood transfusions were given to 16 of the hospitalized patients.

Blood group. In 75 hospitalized patients blood group determinations were performed. The frequency of different blood groups (ABO) was the same in the patients as in the population of Sweden (table 27).

were above the reference value (= abnormal value) and in 19 of these patients the values of alanine aminotransferas (GPT) were above the reference value (= abnormal value) (Table 24)

The frequency of abnormal transaminase values was significantly higher in patients assumed to be alcoholics than in the other patients ($p < 0\ 01$)

Among 39 male patients between 40 and 59 years of age 19 were observed with abnormal values of transaminases (table 24) The frequency of abnormal values of transaminases in this age group was compared with a population study (Tiblin et al 1974) consisting of 803 randomly selected fiftyfour years old men The frequency of abnormal values of transaminases was significantly higher in patients with epistaxis than in this population study ($p < 0\ 01$)

Among the patients with abnormal values of transaminases were found 13 patients with abnormality in one or more of the routine tests of hemostasis two of these patients were habitual bleeders A further 2 patients with abnormal transaminase values were habitual bleeders (table 21)

Routine tests of hemostasis. As shown in tables 21 and 25 abnormal values in at least one of these routine tests of hemostatis were observed in 64 patients (41 %) Abnormal capillary fragility was registered in 15 per cent of the patients. The number of platelets was less than 150 000 platelets/mikroliter in 9 per cent and the bleeding time was abnormal in 15 per cent of the patients. Abnormality in at least one of the blood clotting tests were noted in 23 per cent of the patients.

The values of the bleeding time were abnormal in 20 patients when they were examined the first time In 7 of these patients the platelet count was less than 150 000 platelets/mikroliter All the other 13 patients with abnormal values of the bleeding time had taken acetylsalicylic acid some time during the week before they came to the hospital (table 26)

In 117 patients who had a platelet count of more than 150 000 platelets/mikroliter the bleeding time was measured according to Duke The bleeding time was significantly longer ($p < 0\ 01$) among the patients who had taken acetylsalicylic acid than among those who had not (figure 24)

Hemoglobin concentration and reticulocyte count The hemoglobin concentration was mea

history of epistaxis in a significantly higher frequency than the other patients. The frequency of abnormality in one or more of the routine tests of hemostasis was not higher in patients with a family history of epistaxis than in the other patients, indicating that it might be localized defects in the nasal vessels that are inherited.

The frequency of abnormal values in routine tests of hemostasis was not higher in the habitual bleeders than in the other patients indicating that habitual bleedings also might be due to localized defects in the nasal vessels.

It is impossible to conclude whether any of the different diseases observed in the patients were predisposing to occasional epistaxis. In patients with macroglobulinemia Waldenström, Morbus Osler and some nasal diseases it is reasonable to anticipate a predisposition for habitual bleedings.

The laboratory methods used to detect potent acute bacterial infections were found to be poor indicators. This was obvious from the fact that only four of ten patients with clinically diagnosed acute sinusitis showed laboratory signs of a potent acute bacterial infection. With these methods it was thus impossible to separate viral upper respiratory infections from potent acute bacterial upper respiratory infections. The reason for such a separation also disappeared when it was shown in the histological study of the nasal mucosa (chapter 4 D) that severe inflammatory reactions in the nasal mucosa were observed in patients without histories of upper respiratory infections.

The frequency of abnormal transaminase values was significantly higher in male patients between 40 and 59 years old than in a population sample consisting 54 years old men. Men in this age group with abnormal transaminase values might be predisposed to occasional nose bleedings. The highest frequency of abnormal transaminase values was observed in patients assumed to be alcoholics indicating that it was abuse of alcohol that gave the abnormal transaminase values in some of the patients. There are however many other diseases which might give abnormal values of transaminases. No search for such diseases was carried out.

The frequency of patients with defects in the hemostasis have been studied by other investigators (table 1). Lasber and Heinrich (1960) observed that 75 per cent and Maurer and Rahl (1965) noted that 100 per cent of the examined patients had defects in the hemostasis. When the patients in this study were tested with routine tests of hemostasis it was found that 41 per cent of the patients had defects in the hemostasis.

Acetylsalicylic acid irreversible impair platelet aggregation (Cronberg et al 1970). The normal survival time of platelets is ten days and as little as 0.5 g (one tablet) of acetylsalicylic acid may cause disturbed platelet function and impair the primary hemostasis for several days. The effect of the impaired platelet function can be studied by measuring the bleeding time.

As mentioned in chapter 4 D the frequency of histories of intake of acetylsalicylic acid was significantly higher in patients with epistaxis than in the population sample. When the effect of acetylsalicylic acid on the platelets was studied, it was found that all patients with prolonged bleeding time (Duke) and normal platelet count had taken acetylsalicylic acid some time during the previous week. It was also possible to demonstrate that the bleeding time was significantly longer in patients who had taken acetylsalicylic acid than in the other patients. That acetylsalicylic acid might give prolonged bleeding time has been previously shown by Weiss et al (1968), Mielke et al (1969).

When the patients were treated they had already bled during different long periods of time. The exact blood loss during the bleeding period was thus difficult to estimate. When the hemoglobin concentration was determined 2 to 4 days after the bleeding was finally arrested hemoglobin values less than the reference values were found in 43 per cent of the out patients and 73 per cent of the hospitalized patients. Most patients had an increase of reticulocyte count 4 to 8 days after the bleeding was finally arrested indicating that the measured low hemoglobin values were associated with the actual bleeding. As a consequence of the high frequency of low hemoglobin values the risk of getting sideropenia must be stressed and iron therapy recommended.

There has been reported a higher frequency of blood type O in patients with bleeding tendency than in other patients (Korsan-Bengtsen et al 1972).

No corresponding association between blood type and epistaxis was noted in the hospitalized patients in this study. A reason for this might be that the number of patients studied was too small.

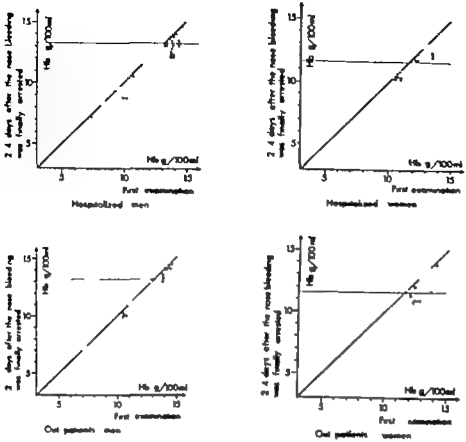

Figure 25 26 27 and 28 Hemoglobin concentration in g/100 ml.

The reason for such a separation also disappeared when it was shown in the histological study of the nasal mucosa (chapter 4 D) that severe inflammatory reactions in the nasal mucosa were observed in patients without histories of upper respiratory infections.

The frequency of abnormal transaminase values was significantly higher in male patients between 40 and 59 years old than in a population sample consisting 54 years old men. Men in this age group with abnormal transaminase values might be predisposed to occasional nose bleedings. The highest frequency of abnormal transaminase values was observed in patients assumed to be alcoholics indicating that it was abuse of alcohol that gave the abnormal transaminase values in some of the patients. There are however many other diseases which might give abnormal values of transaminases. No search for such diseases was carried out.

The frequency of patients with defects in the hemostasis have been studied by other investigators (table 1). Laeber and Heinrich (1960) observed that 75 per cent and Manner and Rahl (1965) noted that 100 per cent of the examined patients had defects in the hemostasis. When the patients in this study were tested with routine tests of hemostasis it was found that 41 per cent of the patients had defects in the hemostasis

Acetylsalicylic acid irreversible impair platelet aggregation (Cronberg et al 1970). The normal survival time of platelets is ten days and as little as 0.5 g (one tablet) of acetylsalicylic acid may cause disturbed platelet function and impair the primary hemostasis for several days. The effect of the impaired platelet function can be studied by measuring the bleeding time

As mentioned in chapter 4 D the frequency of histories of intake of acetylsalicylic acid was significantly higher in patients with epistaxis than in the population sample. When the effect of acetylsalicylic acid on the platelets was studied it was found that all patients with prolonged bleeding time (Duke) and normal platelet count had taken acetylsalicylic acid some time during the previous week. It was also possible to demonstrate that the bleeding time was significantly longer in patients who had taken acetylsalicylic acid than in the other patients. That acetylsalicylic acid might give prolonged bleeding time has been previously shown by Weiss et al (1968), Mielke et al (1969).

When the patients were treated they had already bled during different long periods of time. The exact blood loss during the bleeding period was thus difficult to estimate. When the hemoglobin concentration was determined 2 to 4 days after the bleeding was finally arrested hemoglobin values less than the reference values were found in 43 per cent of the out patients and 73 per cent of the hospitalized patients. Most patients had an increase of reticulocyte count 4 to 8 days after the bleeding was finally arrested indicating that the measured low hemoglobin values were associated with the actual bleeding. As a consequence of the high frequency of low hemoglobin values the risk of getting sideropenia must be stressed and iron therapy recommended.

There has been reported a higher frequency of blood type O in patients with bleeding tendency than in other patients (Korsan-Bengtsen et al 1972).

No corresponding association between blood type and epistaxis was noted in the hospitalized patients in this study. A reason for this might be that the number of patients studied was too small

Conclusions

Family histories of epistaxis were correlated to habitual bleedings but not to demonstrable defects in the hemostasis Neither were habitual bleedings correlated to demonstrable defects in the hemostasis.

In 41 per cent of the patients abnormal values *in at least one of the routine tests of hemostasis* were observed.

The bleeding time was significantly longer in patients who had taken acetylsalicylic acid than in the other patients. All patients with normal platelet count and abnormal bleeding time had *taken acetylsalicylic* acid

The measured hemoglobin values indicated that 43 per cent of the out patients and 73 per cent of the hospitalized patients were anemic.

H. Fibrinolytic activity in bacterial strains

The presence of fibrinolytically active bacterial strains in the nose and throat in patients with epistaxis have not earlier been reported If such strains could be isolated when the patients bled their presence might be an alternative explanation of repeated epistaxis

The extensively examined patients" (chapter 2) were studied with the following methods bacterial isolation (chapter 3 E) and a method for determination of fibrinolytic activity in bacterial strains (chapter 3 I)

Results

Bacterial strains. In 135 of the bleeding patients samples for bacterial growth were taken from the nose and throat when the patients bled In 36 patients (27 %) strains of staphylococcus aureus or beta-hemolytic streptococci were *isolated*

After two to three week a second sample was taken from all patients. This time strains of staphylococcus aureus or beta hemolytic streptococci were isolated from 22 patients. Altogether 46 patients had strains of staphylococcus aureus or beta hemolytic streptococci when they were bleeding and/or some weeks later (table 28)

From these 46 patients were thus isolated 53 strains of staphylococcus aureus and 11 strains of *beta-hemolytic streptococci All these 64 bacterial* strains were tested for fibrinolytic activity

Before the strains were tested the bacterial growth was estimated by registration of the turbidity in the culture The optical density in the cultures varied between 0 34 and 1 15 In 57 of *the cultures the optical density was 0 71 to 1.0*

Fibrinolytic activity The fibrinolytic activity of the strains from 46 patients was tested. It was found that 12 patients had strains with fibrinolytic activity Only four of these patients had had an upper respiratory infection during the previous week. From 9 patients fibrinolytic strains were only isolated when the patients had epistaxis. From 2 patients fibrinolytic strains were isolated during the epistaxis period as well as some weeks *later One patient had a fibrinolytic strain* only when he was examined some weeks after the bleeding. Unfortunately no samples were taken for bacterial cultivation when this patient had epistaxis.

Fibrinolytic activity was found in [illegible] strains of staphylococcus aureus and in [illegible] strains of *beta hemolytic streptococci (table 29) In 6* of these patients the isolated strains must be regarded as fibrinolytically highly potent as the activity was equally high as that of a streptococcal strain usually employed in the production of streptokinase for commercial purposes

In one experiment the relation between *bacterial growth and registered* fibrinolytic activity was studied in the reference strain When the growth as indicated by the optical density was

Table 28. Number of patients with bacterial strains of staphylococcus aureus (st.a.) and beta-hemolytic streptococci (h.str.)

	Number of patients with			
	st.a.	h.str.	st.a. + h.str	One or more strain
Only when the patients bled (I)	20	2	2	24
Only some week later (II)	*9*	1	0	10
On both occasions (I + II)	*9*	*1*	2	12

within the limits of the tested strains no definite difference in fibrinolytic activity was observed.

Comments

In 11 patients (8 per cent of all tested patients) fibrinolytically active bacterial strains were found when the patients bled.

A fibrinolytic bacterial strain present in the nose of a patient with epistaxis produces kinase which might dissolve formed blood clots in ruptured nasal vessels. In this way the bleeding might start again. The split products of the fibrinolysis might also inhibit new clot forming (Kowalski 1968).

Although only few fibrinolytic bacterial strains were found their presence illustrates the possibility that fibrinolytically active bacterial strains might be involved in the hemostasis of epistaxis.

Conclusion

During the bleeding period fibrinolytically active bacterial strains were found in 8 per cent of all examined patients with epistaxis. In 4 per cent of all patients the fibrinolytic strains were highly potent. The presence of such bacterial strains might be an alternative explanation of repeated epistaxis.

I. Fibrinolytic activity in euglobulin precipitate from blood plasma

The spontaneous fibrinolytic activity in blood is increased after emotional stress (Fearnley 1965). It is a common clinical observation that patients with epistaxis are upset, scared and frightend owing to the bleeding from the nose. This emotional stress might increase the spontaneous fibrinolytic activity in blood.

In this study the spontaneous fibrinolytic activity in euglobulin precipitate from plasma was measured in nose bleeding patients when they bled and some weeks later. The fibrinolytic activity releasable from the vessel wall after venous occlusion was also studied in patients with epistaxis as well as in control subjects.

Study groups. The spontaneous fibrinolytic activity was studied in 45 patients. Two examinations were carried out, the first when the patient was bleeding and the second 9 to 30 days later. In 10 patients the spontaneous fibrinolytic activity was followed with repeated tests.

Table 29. Fibrinolytic activity in bacterial strains found in the examined patients.

The fibrinolytic activity in euglobulin precipitate from plasma after venous occlusion was studied in 12 patients selected at random during the autumn 1971 (Table 30). Two examinations were performed the first when the patients bled from the nose and the second one month later

To serve as a control group 12 healthy subjects of the same sex and about the same age as the patients were tested with venous occlusion tests (table 30)

Methods The fibrinolytic activity in euglobulin precipitate from plasma was determined according to the method described in chapter 3 k. All patients were tested between 9 and 12 a m

The *fibrinolytic capacity* of the vessel wall means the fibrinolytic activity in resuspended euglobulin precipitate after venous occlusion (Robertsson et al 1971)

The difference in mm² lysis area between the fibrinolytic activity in resuspended euglobulin precipitate after venous occlusion and the spontaneous fibrinolytic activity before venous occlusion is called the *releasable blood activity*

Statistical analyses. The patients and the controls were divided into four homogenous subgroups with regard to sex and age in order to avoid the influence of sex and age in the correlations The statistical analyses were performed with Fisher s test within each group (Oden and Wedel 1973) The results of the subgroups were then pooled by a special technique (Oden and Wedel 1974) to get a general conclusion about the correlations in the study groups. A difference between the study groups is regarded as significant when $p < 0.05$

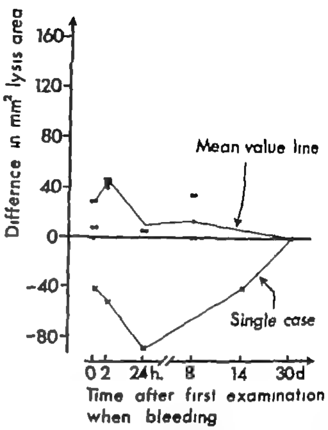

Figure 34 Spontaneous fibrinolytic activity in 10 patients followed by repeated tests. In each patient the value determined one month after the actual bleeding was regarded as resting value and marked with zero. The differences in lysis area between the resting value and the values measured on the other test occasions were calculated and are presented as dots in the figure. The mean values of the different test occasions are connected in the figure One patient whose reactions differed from the other patients is marked separately

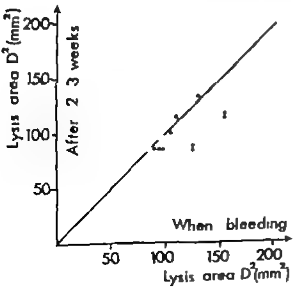

Figure 33 Spontaneous fibrinolytic activity in 45 patients with epistaxis when bleeding and 2–3 weeks late

Results

Spontaneous fibrinolytic activity In 45 patients tested the fibrinolytic activity was significantly higher ($p < 0.001$) when the patients bled compared with some weeks later (figure 33)

In 8 patients followed with repeated tests the fibrinolytic activity was higher when the patients bled than one month later In one patient the fibrinolytic activity was equal on both occasions (figure 34) When the values of these 9 patients were followed after the actual bleeding it was noted that the fibrinolytic activity had increased after 2 hours and decreased after 24 hours

There was no difference in the spontaneous fibrinolytic activity between 12 patients (in whom venous occlusion tests were also performed) one month after the actual bleeding and 12 control subjects (Table 30).

Fibrinolytic activity after venous occlusion. The releasable blood activity was significantly higher in the patients one month after the actual bleeding (when they were resting) than in the control subjects. (figure 35).

When the releasable blood activity determined at the first examination of the patients, was correlated to the duration of the nose bleeding the following was observed. Among the seven patients, who had bled less than four hours before the first examination, the releasable blood activity was significantly lower when the patients bled than one month later (figure 35).

Among the remaining five patients, who had bled more than six hours before the first examination the releasable blood activity was higher when the patients bled than one month later (figure 35).

Comments

It is known that the spontaneous fibrinolytic activity in blood has a diurnal variation (Fearnley 1965). All examinations in this study were performed between 9 and 12 a.m. in order to exclude these diurnal variations.

Most likely the increase of spontaneous fibrinolytic activity when bleeding and 2 hours later is explained by emotional stress in association with the bleeding and probably also stress owing to the blood loss.

The fibrinolytic activity releasable from the vessel wall after venous occlusion was measured and correlated to the duration of the nosebleeding. All patients who had bled less than 4 hours could release less fibrinolytic activity when they bled than when they were controlled after one month. As a hypothesis it might be assumed that the releasable activity in these patients was evacuated. Patients who had bled more than six hours could release more fibrinolytic activity when they bled than after one month. The reason of this is unknown.

Conclusions

In patients with epistaxis the spontaneous fibrinolytic activity in euglobulin precipitate from plasma was significantly higher when the patients bled than some weeks later.

The releasable fibrinolytic activity from the

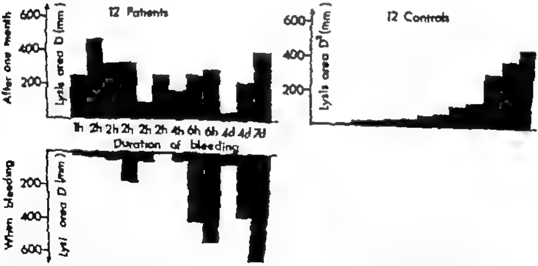

Figure 35. The releasable fibrinolytic activity from the vessel wall after venous occlusion. The patients are presented in sequence according to the duration of the nose bleeding. The height of the upturned staples show the activity after one month (resting values) and the downturned ones the activity when bleeding. The controls are presented in sequence according to the value of the activity.

The fibrinolytic activity in euglobulin precipitate from plasma after venous occlusion was studied in 12 patients selected at random during the autumn 1971 (Table 30). Two examinations were performed the first when the patients bled from the nose and the second one month later

To serve as a control group 12 healthy subjects of the same sex and about the same age as the patients were tested with venous occlusion tests (table 30)

Methods The fibrinolytic activity in euglobulin precipitate from plasma was determined according to the method described in chapter 3 k All patients were tested between 9 and 12 a m

The *fibrinolytic capacity* of the vessel wall means the fibrinolytic activity in resuspended euglobulin precipitate after venous occlusion (Robertsson et al 1971)

The difference in mm2 lysis area between the fibrinolytic activity in resuspended euglobulin precipitate after venous occlusion and the spontaneous fibrinolytic activity before venous occlusion is called the *releasable blood activity*

Statistical analyses The patients and the controls were divided into four homogenous subgroups with regard to sex and age in order to avoid the influence of sex and age in the correlations The statistical analyses were performed with Fisher s test within each group (Oden and Wedel 1973) The results of the subgroups were then pooled by a special technique (Oden and Wedel 1974) to get a general conclusion about the correlations in the study groups. A difference between the study groups is regarded as significant when $p < 0.05$

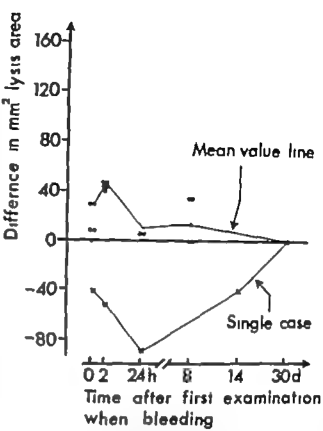

Figure 34 Spontaneous fibrinolytic activity in 10 patients followed by repeated tests. In each patient the value determined one month after the actual bleeding was regarded as resting value and marked with zero. The differences in lysis area between the resting value and the values measured on the other test occasions were calculated and are presented a dots in the figure Th mean values of the different test occa ions are connected in the figure One patient whose reactions differed from the other patients is marked separately

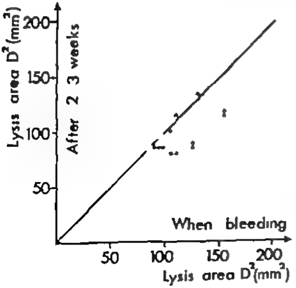

Figure 33 Spontaneous fibrinolytic activity in 45 patients with epistaxis when bleeding and 2–3 weeks lat r

Results

Spontaneous fibrinolytic activity In 45 patients tested the fibrinolytic activity was significantly higher ($p < 0.001$) when the patients bled compared with some weeks later (figure 33)

In 8 patients followed with repeated tests the fibrinolytic activity was higher when the patients bled than one month later In one patient the fibrinolytic activity was equal on both occasions (figure 34) When the values of these 9 patients were followed after the actual bleeding it was noted that the fibrinolytic activity had increased after 2 hours and decreased after 24 hours

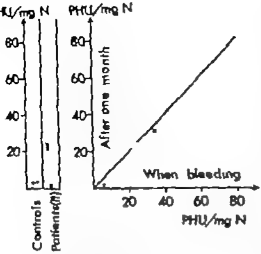

Figure 36 Total fibrinolytic activity in the nasal mucosa. The values of 12 patients with epistaxis (x) when bleeding (I) and one month later (II). The values of 12 control subjects ( ).

acid stable fibrinolytic activity as PHUa per mg nitrogen of the nasal mucosa.

The statistical analyses were performed as described in chapter 4 L. A difference is regarded as significant when $p < 0.05$

Results

Total fibrinolytic activity In the 12 patients the total fibrinolytic activity in the nasal mucosa was

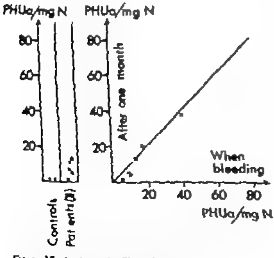

Figure 37 Acid stable fibrinolytic activity in the nasal mucosa. The values of 12 patients with epistaxis (x) when bleeding (I) and one month later (II). The values of 12 control subjects ( ).

significantly higher when the patients bled than one month later. There was no significant difference between the control group and the patients one month after the actual bleeding (figure 36).

Acid stable fibrinolytic activity In the 12 patients the acid stable fibrinolytic activity in the nasal mucosa was higher when the patients bled than one month later. The difference was however not significant. There was no significant difference between the control group and the patients one month after the actual bleeding (figure 37)

Comments

The higher total fibrinolytic activity in the nasal mucosa when the patients bled from the nose compared with one month later might be either a localized phenomenon in the nasal mucosa or it might be a recorded sign of a generalized increase of tissue activity when the patients were bleeding.

Todd (1959) showed that the fibrinolytic activity in the tissue was localized in endothelial cells. Fearnly (1965) suggested that the blood activator was derived from the venous endothelium and that the venous system had an active secretory function. Nilsson et al (1969) supposed that the tissue activator was released in a labile form into the blood stream.

A high fibrinolytic activity in the nasal mucosa during the bleeding period might thus result in a high local activity in the blood stream and give a too quick dissolution of blood clots in the nasal vessels

Conclusion

The total fibrinolytic activity in the nasal mucosa was significantly higher in patients with epistaxis when they bled compared with one month later. This increase of total fibrinolytic activity when bleeding might be of importance as an explanation of recurrent nose bleedings.

L. A double blind study to evaluate the effect on epistaxis with oral administration of the antifibrinolytic drug tranexamic acid (Cyklokapron®)

In order to study the effect of an antifibrinolytic drug on recurrent nose bleedings a double blind study with tranexamic acid (Cyklokapron®) was performed on hospitalized patients with epistaxis.

vessel wall after venous occlusion was significantly higher in the patients, one month after the bleeding episode than in the control subjects.

K. Fibrinolytic activity in the nasal mucosa

The fibrinolytic activity in the nasal mucosa has been studied by Buch Rasmussen (1966). When the fibrinolytic activity in the nasal mucosa from two patients with epistaxis, was compared with the activity in the mucosa from five control subjects no difference in fibrinolytic activity was found

In this study patients with epistaxis were studied when bleeding and one month later The purpose was to investigate whether the fibrinolytic activity in the nasal mucosa was changed when the patients bled

The fibrinolytic activity in the patients was also compared with the activity in control subjects in order to study if the patients differed from the control subjects.

Study groups. The fibrinolytic activity in the nasal mucosa was studied in 12 patients selected at random during the autumn 1971 (table 31) Two examinations were performed on each patient the first when the patient was bleeding and the second one month later

To serve as a control group 12 healthy subjects of the same sex and about the same age as the patients were examined (table 31)

Methods. The fibrinolytic activity in the nasal mucosa was determined according to the method presented in chapter 3 L. All examinations were performed between 9 and 12 a.m. A small piece of nasal mucosa was taken without anaesthesia from the anterior part of the inferior concha. In the patients the two biopsies were taken from the nasal cavity opposite to the bleeding, some mm apart from each other The biopsies were immediately frozen to −20°C and kept frozen until they were analysed

The total fibrinolytic activity is presented as PHU per mg nitrogen of the nasal mucosa and the

he received the bottle with his number and was told to take the tablets as in the hospital.

The dosage was 1 g three times a day. Later investigations on for example contration operations (Rybo and Westerberg 1972) have shown that a dosage of 1.5 g three times a day is preferable when the fibrinlytic activity is to be inhibited.

The tampons in the nose were taken away according to a previously made time table. The water in the Foley catheter balloon was drained 12 to 24 hours after the bleeding had stopped. The catheter was taken away 3 to 6 hours later. If no bleeding occured within 12 to 24 hours the anterior gauze tampon was taken away until fresh blood appeared on the gauze. Every 3 to 6 hours, except during the night, the gauze was taken away until all was out. The patient was sent home 12 to 24 hours later on the following morning.

When a new severe bleeding occured a new posterior and/or anterior tampon was given. These tampons were taken away as previously described.

In other investigations on Cyklokapron® it has been possible to evaluate the effect of treatment by measuring the blood loss (Nilsson and Rybo 1967, Hedlund 1970). In this study it was not possible to evaluate the effect of Cyklokapron® by measuring the blood loss as the patients swallowed a part of the blood they lost.

The effect of the therapy was instead evaluated by using a point scale. When the treatment had begun the severity and the number of recurrent bleedings were registered and given bleeding points. In each patient the bleeding points for the ten days of treatment were then added and presented as total amount of bleeding points.

The recurrent bleedings, which occurred within intervals of twelve hours during the ten days of treatment, were classed twice a day and given the following bleeding points: 0 = no bleeding, 1 = unimportant bleeding, 2 = small bleeding during some minutes, not treated, 4 = repeated small bleedings, not treated, 6 = large bleeding which required local treatment (tampons).

Whether the bleeding was large and requiring new tampons or not, was in daytime determined by the author and at other times by the emergency ENT-doctor at the clinic. One to three days after the drug treatment was finished the patients visited the hospital again. They were examined and

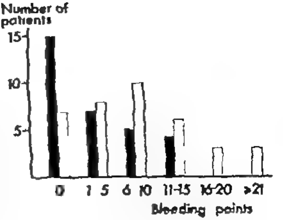

Figure 38. Number of patients with different bleeding points.

questioned whether any bleedings from the nose had occurred during the treatment at home.

The hospitalisation time was used as another criterea on the effect of the treatment. The hospitalisation time depended on whether new bleedings occurred, how quickly the tampons could be taken away and whether new tampons had to be used.

The statistical analyses were performed with contingency tables. All the significances which are presented are at a level $p < 0.01$.

Results

The total amount of bleeding points in each patient was significantly less in patients who received Cyklokapron® than in the patients who received placebo (figure 38).

When the total amount of bleeding points in the two groups of patients were calculated a significant difference was found between the two groups of patients (table 33).

The number of patients with at least one recurrent bleeding after the therapy had started and after the third day of treatment was significantly less in the Cyklokapron® than in the placebo group (table 34).

After the third day of treatment only two patients who received Cyklokapron® had a recurrent bleeding each. One patient had a small

Study group All patients who were hospitalized due to epistaxis from february to december 1971 (at the ENT-clinic Göteborg) were selected for this double blind study Cyklokapron was given to 31 patients and placebo to 37 patients.

The patients who were treated with Cyklokapron® and the patients who received placebo did not differ with regard to histories of upper respiratory infections, intake of acetylsalicylic acid and hypertension (table 3?) The mean age in the two groups was the same as well as the localisation of the bleeding source and the local treatment primarily given

Methods. When the patients came to the hospital the bleeding was arrested with a posterior Foley catheter and/or anterior gauze tampons (chapter 3 C) After the bleedings were arrested the patients were hospitalized.

Assignment of Cyklokapron® tablets of placebo tablets was performed by random numbers and the labels of the bottles bore only the patients serial number (1 2 etc) The administration of tablets began within one hour after hospitalisation. The patients were given Cyklokapron® or placebo during ten days. When a patient left the hospital

questioned whether any bleedings from the nose had occurred during the treatment at home.

The hospitalisation time was used as another criteria on the effect of the treatment. The hospitalisation time depended on whether new bleedings occurred, how quickly the tampons could be taken away and whether new tampons had to be used.

The statistical analyses were performed with contingency tables. All the significances which are presented are at a level $p < 0.01$.

Results

The total amount of bleeding points in each patient was significantly less in patients who received Cyklokapron® than in the patients who received placebo (figure 38).

When the total amount of bleeding points in the two groups of patients were calculated a significant difference was found between the two groups of patients (table 33).

The number of patients with at least one recurrent bleeding after the therapy had started and after the third day of treatment was significantly less in the Cyklokapron® than in the placebo group (table 34).

After the third day of treatment only two patients who received Cyklokapron® had a recurrent bleeding each. One patient had a small

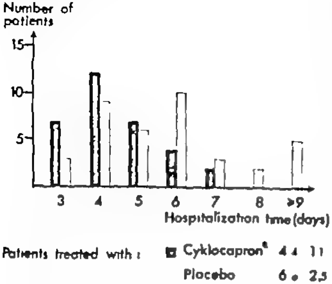

Figure 39 Number of patients with different hospitalisation time

bleeding one day after leaving the hospital and one patient with delirium tremens had a severe bleeding in the hospital on the fourth day of treatment

The hospitalisation time was significantly shorter in the patients who were treated with Cyklokapron® than in those who received placebo (figure 39)

Diarrhoe abdominal pain, nausea and dizziness are mentioned as general side effects of Cyklokapron® (for example Nilsson and Rybo 1967 Andersson and Nilsson 1969).

Many patients in this study had lost a lot of blood before they came to the hospital and were in shock or preshock when examined before hospitalisation. In these patients it was difficult to evaluate general side effects of the treatment.

Table 33. Total amount of bleeding points in the two groups of patients. The bleeding point scale 1 unimportant bleeding 2 small bleeding during some minutes, not treated 4 repeated small bleedings, not treated 6 = large bleeding which required treatment with tampons

	Patients treated with Cyklokapron® Bleeding points 1	2	4	6	Placebo Bleeding points 1	2	4	6
Number of classified bleedings in the group								
Total	26	11	6	6	47	36	19	18
After 3 days therapy	0	1	0	1	18	19	3	7
After 5 days therapy	0	0	0	0	13	4	0	3

Table 34 Number of patients with at least one recurrent bleeding.

	Patients treated with Cyklokapron®	Placebo
Total	16 (52 %)	30 (81 %)
After 3 days therapy	2 (6 %)	15 (41 %)
After 5 days therapy	0	10 (27 %)

During the hospitalisation time none of the patients complained of symptoms which might be taken for general side effects. The most common complains were pains due to the nasal tampons.

Local side effects of the treatment were noted in two patients. One patient who received Cyklokapron® and one patient who received placebo had small synechies in the nose after the treatment was finished. Most probable these synechies depended on the local treatment with tampons.

Comments

From the scientific point of view it might have been preferable to use Cyklokapron® or placebo as the only therapy in this study It would, however not have been possible to justify this ethically Conventional local treatment had to be used together with Cyklokapron® and placebo

The tampons must be regarded as errors in the evaluation of the therapy effect. When the tampons were taken away or moved small bleedings sometimes started. These small bleedings were not registered

An explanation of some of the recurrent bleedings observed during the first three days of therapy might be that the tampons were moved by the doctor or the patient The recurrent bleedings during the first three days were however significantly less in the patients who received Cyklokapron® than in the other patients.

The effect of the therapy in this double blind study was evaluated by the severity and number of recurrent nose bleedings. The recurrent bleedings were classified according to a point scale There have not been any difficulties in determing what bleeding point the patients should have when they were hospitalized. In the period after hospitalisation it has also been possible to classify the recurrent bleedings without difficulties. As shown in the results the patients who were treated with Cyklokapron® had significantly less recurrent nose

bleedings both in severity and number than the patients who received placebo.

Conclusions

In this double blind study with the antifibrinolytic drug tranexamic acid (Cyklokapron®) it was possible to demonstrate that recurrent bleedings in patients with epistaxis were significantly less in number and severity when the patients were treated with Cyklokapron® compared with placebo

It was also observed that the hospitalisation time was significantly shorter when the patients were treated with Cyklokapron® instead of placebo.

Conclusions

In this double blind study with the antifibrinolytic drug tranexamic acid (Cyklokapron®) it was possible to demonstrate that recurrent bleedings in patients with epistaxis were significantly less in number and severity when the patients were treated with Cyklokapron® compared with placebo.

It was also observed that the hospitalisation time was significantly shorter when the patients were treated with Cyklokapron® instead of placebo.

CHAPTER 5

GENERAL DISCUSSION

In the introduction four questions of practical clinical interest were presented

1. Why does a nose bleeding start?
2. What is predisposing to nose bleedings?
3. Why have some nose bleedings a long duration?
4. Why are some nose bleedings recurrent?

All the evidence necessary to give a complete answer to any of these questions are not yet available. The results of the present and of other investigations will however be used in an attempt to discuss the problems as far as possible

1 Why does a nose bleeding start?

A nose bleeding might start after a trauma against the nasal structures of that magnitude that at least one vessel ruptures or it might start "spontaneously"

In 28.5 per cent (322/1118) of the patients in the present investigation the nose bleeding started after different traumas against the nasal structures for example nose picking, nose blowing or a strike against the nose (chapter 4 B)

In 6 5 per cent (72/1118) of the patients the bleeding started in association with physical or psychical exhaustion. The releasing mechanism in these cases is difficult to estimate

In the remaining 65 per cent (724/1118) of the patients the nose bleeding started without any obvious reason

2. What is predisposing to nose bleedings?

a. Predisposing factors localized in the nasal mucosa. It has been shown by Naumann (1961) that inflammatory reactions which were chemically induced in the nasal mucosa of rabbits, caused vessel wall injuries.

In this clinical study nasal mucosa biopsies, taken from the nasal cavity opposite to the bleeding cavity were analysed histologically In all of ten patients with epistaxis histological signs of severe or moderate inflammatory reactions were observed in the nasal mucosa. In the same number of control subjects, without epistaxis, no or only slight histological signs of inflammatory reactions were observed in the biopsies (chapter 4 D). In five of the ten patients from whom nasal mucosa biopsies were taken the inflammatory reactions which were observed probably depended on upper respiratory infections.

A higher frequency of histories of upper respiratory infections was noted in patients with epistaxis than in a population sample (chapter 4 C).

Upper respiratory infections giving inflammatory reactions in the nasal mucosa might predispose to epistaxis if the infection results in vessel wall injuries.

Chemically induced inflammatory reactions in the nasal mucosa giving epistaxis have been observed as an epidemic occupational disease after daily work with gentian violet (Quinby 1968).

b. Predisposing factors localized in the vessel wall. Arteriosclerosis is mentioned by Hara (1962) as an etiological factor of epistaxis.

The walls of the nasal arteries have been studied histologically by Shaheen (1970) In aging individuals he observed a degeneration in the arterial wall characterized by loss of muscle in the tunica media and its replacement of collagen The degenerations were more pronounced in patients who had suffered from epistaxis than in other subjects.

Varicose veins on the nasal septum are sometimes observed in patients with epistaxis. Dohl-

mas (1938), who made serial sections of the nasal mucosa in patients without epistaxis, said that he sometimes found very wide superficial veins with a normal lstima but only a very thin surrounding vessel wall. These pathological changes might predispose to a vessel rupture and nose bleeding.

Patients with Mb Osler who frequently have epistaxis, have pathological changes in the walls of small vessels, which usually contain only endothelial cells (Jahnke 1970).

It has not been systematically studied whether other nasal vessel wall defects than those found in patients with Mb Osler are inherited. In the present investigation it was observed that habitual nose bleeders had a family history of epistaxis in a higher frequency than other nose bleeders (chapter 4 G). It was also noted that the frequency of abnormality in any of the routine tests of hemostasis, were the same in patients with a family history of epistaxis as in the other patients (chapter 4 G). This speech in favour of the hypothesis that localized defects in the vessel walls of the nasal mucosa are inherited.

c. Predisposing factors due to blood flow and pressure. Long lasting abnormalities in blood flow and pressure in the nasal vessels of rabbits gave pathological changes in the vessel walls (Naumann 1961). It is difficult to evaluate to what extent changes in blood flow and pressure in a human nasal vessel might predispose to a vessel rupture. It is also unknown whether the nasal vessels with arteriovenous anastomoses, venous plexus and sinusoidal spaces (chapter 1 E) are more susceptible to changes in blood flow and pressure than other vessels.

Increased viscosity of the blood and impaired circulation in small vessels, giving thrombosis and hemorrhages in retinal veins was observed in patients with macroglobulinemia Waldenstrom (Spitter 1959). In this disease repeated spontaneous small nose bleedings are frequently noted (Leading article Brit Med J 1965).

Hypertension is mentioned as an etiological factor of epistaxis in several clinical studies about epistaxis (chapter 1 B). Shaheen (1970) and Weiss (1972) could, however not find any correlation between hypertension and epistaxis. The conclusions from the present study confirm their observations.

In chapter 4 E is shown that the frequency of histories of hypertension was not higher in our patients with epistaxis than in a population sample. When the blood pressure was measured in 155 patients with epistaxis it was found that the distribution of different blood pressures was the same in the patients group as in a population sample (chapter 4 F). The frequency of distinct arterial bleedings from the nose was the same in patients with a history of epistaxis as in other patients (chapter 4 E).

A temporary increase of the blood pressure might, however result in a vessel rupture. Such a temporary increase might partly explain the start of nose bleedings in association with physical or psychical exhaustion.

d. Predisposing factors due to impaired hemostasis. As mentioned in the review of the literature, epistaxis is a common symptom in different defects of the hemostasis (Nilsson 1971, Biggs 1972). These defects might be due to diseases as for example acquired thrombocytopenia, inherited defects of coagulation factors or treatment with different drugs as dicumarol, heparin, streptokinase or acetylsalicylic acid. It is assumed that subjects with severe defects are more predisposed to bleeding symptoms than subjects with mild defects.

The significance of acetylsalicylic acid as a predisposing factor of nose bleedings has not been systematically studied before.

A dosis of 0.5 g acetylsalicylic acid can impair the platelet aggregation during several days (Cronberg et al 1970). It was observed by Mielke et al (1968) that the bleeding time was significantly prolonged after consumption of acetylsalicylic acid. In this clinical study it was noted that the bleeding time (according to Duke) was significantly longer in patients who had taken acetylsalicylic acid, compared with other nose bleeding patients (chapter 4 G).

Croft and Wood (1967) showed that acetylsalicylic acid can give gastric bleedings. In 80 per cent of the subjects studied, who received aspirin was found a blood loss in the stool of 2 to 10 ml per day. In 10 per cent of the subjects the blood loss

was more than 10 ml per day A blood loss of less than 2 ml per day which was regarded as normal, was only observed in 10 per cent of the tested subjects.

Parry and Wood (1967) observed that 94 per cent (33/35) of the patients with acute gastric bleeding had taken aspirin during the previous week.

In patients with von Willebrand's syndrome who frequently have epistaxis, Quick (1968) observed that epistaxis in some patients started spontaneously after consumption of aspirin.

In the present investigation it was noted that patients with epistaxis had taken acetylsalicylic *acid in a significantly higher frequency than* subjects in a control group (chapter 4 C)

Subjects in a population sample who had bled from the nose the previous week, had taken acetylsalicylic acid when they had an upper respiratory infection in a significantly higher frequency than other subjects (chapter 4 C).

These clinical observations support the hypothesis that acetylsalicylic acid predisposes to nose bleedings.

3 Why have some nose bleedings a long duration?

Most cases of nose bleedings are arrested spontaneously In a population sample 60 per cent of the subjects had had epistaxis at least once during lifetime but only 8 per cent of the subjects had *been treated for epistaxis by a doctor (chapter 4 A)*

There are different explanations of a long duration of a nose bleeding anatomical and physiological conditions in the nose changes in the functions of the vessel wall impaired form*ation of platelet plugs, impaired coagulation,* increased fibrinolysis and mechanical influences on the blood clot formation.

a. Anatomical and physiological conditions in the nose The vessel wall in subepithelial capillaries and small veins is thin and without muscular *tissue (Messerklinger 1958). These vessels are thus* supposed to lack ability of active contraction

According to Weddel et al (1945) large septal vessels, embedded in the mucosa, can not contract as easily as other vessels after laceration

b. Changes in the function of the vessel wall. In patients with Mb Osler the abnormal vessel walls do not contain any muscular layer (Jahnke 1970). The ability to vasoconstriction is lost in these abnormal vessels, which might give prolonged bleeding after vessel ruptures.

The prevention of petechial formation after capillary fragility tests is dependent upon the integrity of the capillary wall but also upon a normal platelet function In the present investigation abnormal capillary fragility was observed in 15 per cent (19/135) of the examined patients with epistaxis (chapter 4 G).

c. Impaired formation of platelet plugs. The bleeding time is a measure of the ability to form a *local platelet plug after a standardized skin incision* It was found that 15 *per cent (20/138)* of *the studied patients had abnormal bleeding time* indicating impaired platelet function (chapter 4 G)

The number of platelets was below the reference value in 9 per cent (13/149) of the patients examined (chapter 4 G)

d. Impaired coagulation. In other investigations impaired hemostasis were noted in one to a hundred per cent of the patients with epistaxis (chapter 1 B)

In this investigation it was found that 23 per cent (35/151) of the patients examined had impaired coagulation when tested with four different routine coagulation tests (chapter 4 G). It was *also noted* that 3 of 155 patients examined had taken dicumarol.

The split products after fibrinolysis impair blood clotting (Kowalski 1968 Larrieu et al 1972) The increased fibrinolytic activity in blood and nasal mucosa and the presence of fibrinolytically active bacterial strains in patients with epistaxis (chapter 4 H, I K) might result *in split* products capable of impairing the coagulation in nose bleeding patients.

e Mechanical influences on the blood clot formation. During clot formation after vessel ruptures in the nose movements of the nasal mucosa (and the immature clot) might interfere with the clot formation These movements can be due to breathing through *the nose nose blowing,* sneezing, a finger or a piece of cotton introduced *into the bleeding nasal cavity*

4. Why are some nose bleedings recurrent?

In many patients with epistaxis the nose bleeding starts again spontaneously some hours to some days after it has been arrested. Explanations of these secondary released nose bleedings might be that the blood clot is moved away or locally dissolved. It is also possible that the bleeding comes from a new bleeding source.

a Mechanical influences on the blood clot. The clot can be mov ed away due to breathing through the nose, etcetera. A newly formed blood clot or a weak blood clot due to impaired coagulation is probably more susceptible to mechanical influences. An increased blood flow or increased blood pressure might as well wash away the clot.

b Dissolution of the blood clot. The dissolution of the blood clot depends on fibrinolysis. Fibrinolysis is an enzymatic break down of fibrin by plasmin. Plasminogen, which is a precursor to plasmin, can be activated to plasmin by different activator systems (chapter 1 F).

In the present investigation three different plasminogen activator systems were studied: bacterial activator, blood activator and tissue activator in the nasal mucosa. The significance of these activator systems in patients with epistaxis have hitherto not been systematically studied.

I *Fibrinolytic activity in bacterial strains.* From eleven of 135 examined patients with epistaxis (8 %) bacterial strains with ability to produce streptokinase or staphylokinase were isolated during the nasal bleeding (chapter 4 H). In these patients it seems reasonable to assume that the fibrinolytically active bacterial strains had dissolved blood cl ts in the nose and thus released recurrent bleedings.

II *Fibrinolytic activity in the blood.* In this clinical study the spontaneous fibrinolytic activity in the plasma was measured in 45 patients (chapter 4 I). The fibrinolytic activity was found to be significantly higher when the patients were bleeding than some weeks later. A high activity during the bleeding period might dissolve blood clots in the nose quickly.

It was also observed that the fibrinolytic activity releasable from the vessel wall after venous occlusion was significantly higher in 12 patients, examined one month after the nose bleeding, than in 12 control subjects (chapter 4 I). A high ability to release fibrinolytic activity might give an increased activity in the blood during the bleeding period and result in a quick dissolution of formed blood clots.

III *Fibrinolytic activity in the nasal mucosa.* With the aid of a new method for determination of tissue plasminogen activator in small pieces of nasal mucosa (chapter 3 L) the fibrinolytic activity was measured in 12 patients with epistaxis.

The total fibrinolytic activity in the nasal mucosa was significantly higher when the patients were bleeding than one month later (chapter 4 K). This increased fibrinolytic activity could upset the hemostatic balance and give a too quick dissolution of formed blood clots which might result in a recurrent nose bleeding.

Recently it has been reported by Kwaan and Silverman (1973) studying patients with Mb Osler that the fibrinolytic activity was higher in telangiectatic small vessels than in normal vessels in the patients. This finding suggest a role of fibrinolysis in patients with Mb Osler.

IV *Inhibition of fibrinolytic activity.* In order to investigate whether an inhibition of fibrinolysis would decrease the number of recurrent nose bleedings a double blind study was performed with the antifibrinolytic drug *tranexamic acid* (Cyklokapron®). Those patients in whom the fibrinolytic activity was inhibited with Cyklokapron® had significantly less recurrent bleedings and less severe bleedings than patients treated with placebo (chapter 4 L).

The hospitalization time was also significantly shorter in patients treated with Cyklokapron® compared with patients treated with placebo.

The results of this double blind study indicate that inhibition of fibrinolysis is of great importance to prevent recurrent epistaxis.

was more than 10 ml per day A blood loss of less than 2 ml per day which was regarded as normal. was only observed in 10 per cent of the tested subjects.

Parry and Wood (1967) observed that 94 per cent (33/35) of the patients with acute gastric bleeding had taken aspirin during the previous week.

In patients with von Willebrand's syndrome who frequently have epistaxis Quick (1968) observed that epistaxis in some patients started spontaneously after consumption of aspirin.

In the present investigation it was noted that patients with epistaxis had taken acetylsalicylic acid in a significantly higher frequency than subjects in a control group (chapter 4 C).

Subjects in a population sample who had bled from the nose the previous week, had taken acetylsalicylic acid when they had an upper respiratory infection in a significantly higher frequency than other subjects (chapter 4 C)

These clinical observations support the hypothesis that acetylsalicylic acid predisposes to nose bleedings.

3 Why have some nose bleedings a long duration?

Most cases of nose bleedings are arrested spontaneously In a population sample 60 per cent of the subjects had had epistaxis at least once during lifetime but only 6 per cent of the subjects had been treated for epistaxis by a doctor (chapter 4 A).

There are different explanations of a long duration of a nose bleeding anatomical and physiological conditions in the nose changes in the functions of the vessel wall, impaired formation of platelet plugs, impaired coagulation, increased fibrinolysis and mechanical influences on the blood clot formation.

a. Anatomical and physiological conditions in the nose The vessel wall in subepithelial capillaries and small veins is thin and without muscular tissue (Messerkling 1958). These vessels are thus supposed to lack ability of active contraction

According to Weddel et al (1945) large septal vessels, embedded in the mucosa, can not contract as easily as other vessels after laceration

b. Changes in the function of the vessel wall. In patients with Mb Osler the abnormal vessel walls do not contain any muscular layer (Jahnke 1970). The ability to vasoconstriction is lost in these abnormal vessels, which might give prolonged bleeding after vessel ruptures.

The prevention of petechial formation after capillary fragility tests is dependent upon the integrity of the capillary wall but also upon a normal platelet function. In the present investigation abnormal capillary fragility was observed in 15 per cent (19/135) of the examined patients with epistaxis (chapter 4 G).

c Impaired formation of platelet plugs. The bleeding time is a measure of the ability to form a local platelet plug after a standardized skin incision. It was found that 15 per cent (20/138) of the studied patients had abnormal bleeding time indicating impaired platelet function (chapter 4 G)

The number of platelets was below the reference value in 9 per cent (13/149) of the patients examined (chapter 4 G)

d. Impaired coagulation. In other investigations impaired hemostasis were noted in one to a hundred per cent of the patients with epistaxis (chapter 1 B)

In this investigation it was found that 23 per cent (35/151) of the patients examined had impaired coagulation when tested with four different routine coagulation tests (chapter 4 G). It was also noted that 3 of 155 patients examined had taken dicumarol.

The split products after fibrinolysis impair blood clotting (Kowalski 1968 Larrieu et al 1972). The increased fibrinolytic activity in blood and nasal mucosa and the presence of fibrinolytically active bacterial strains in patients with epistaxis (chapter 4 H, I K) might result in split products capable of impairing the coagulation in nose bleeding patients.

e Mechanical influences on the blood clot formation. During clot formation after vessel ruptures in the nose movements of the nasal mucosa (and the immature clot) might interfere with the clot formation These movements can be due to breathing through the nose nose blowing, sneezing, a finger or a piece of cotton introduced into the bleeding nasal cavity

ACKNOWLEDGEMENTS

The present study has been carried out at the Department of Otorhinolaryngology and the Coagulation laboratory Department of Medicine II, University of Goteborg, Sweden.

My interest in epistaxis was awoken after I had read Professor Videbaek s textbook of hematology in which he mentioned that epistaxis was a common symptom in different hematological diseases

I wish to express my gratitude to my chief, Professor Gosta Herberts, M.D head of the Department of Otorhinolaryngology Goteborg for his unfailing interest in my work, for stimulating discussions and constant encouragement.

To Docent Kristoffer Korsan-Bengtsen, M.D head of the Coagulation laboratory Goteborg, I express my openhearted thanks for his interest, criticism and encouragement, which has been of invaluable help during the entire investigation.

I also offer my sincere thanks to the staff of AB KABI, Sweden and especially to the former head of the research department docent Hans Dahlstrom, M.D., who believed in my hypothesis about the significance of fibrinolysis in epistaxis and with grants from AB KABI supported the methodological investigations. To Karl-Åke Callert, Hans Kjellman, Ragnar Lundén and Bertil Åberg at AB KABI, I also wish to express my gratitude for stimulating discussions and advice.

My sincere gratitude goes to my collegues both inside and outside the clinic, who have helped me with the registration of the patients, the staff at the clinic especially the laboratory assistants Anna Widlund and Olga Hed-Johansson the patients and the subjects both in the control groups and the population sample who all helped me in realizing these studies.

I also wish to thank.

Computer expert Pelle Hasselskog for stimulating discussions and skilful advice in planing the investigation for computer analyses and Christer Lövkrantz for performing the analyses.

Professor Stig Holm, M.D who kindly stored the bacterial strains, helped me with the determination of fibrinolytic activity in them and reviewed the manuscript concerning this part of the study

Assistant Professor Göran Hansson, M.D who kindly helped me with the histological analyses of the biopsies from the nasal mucosa and reviewed the manuscript about this part of the study

Docent Pål-Henry Jeppsson, M.D and docent Olle Hallén M.D for constructive criticism and review of the clinical part of my manuscript.

Docent Jorgen Lindstrom, M.D., for his help with the anatomical review

Docents Johan Ygge M.D Goran Rybo M.D., Ann-Catrine Teger Nilsson, M.D and John Gormsen M D for review of the fibrinolytic part of the investigations.

Docent Lars Wilhelmsen, M.D for kind advice and constructive criticism about hypertension and blood pressure registration.

Docent Rudolf Jagenburg, M.D., for helpful advice in evaluating the laboratory data.

Laboratory assistant Ulla Börjesson, who carried out the methodological experiments and the determinations of fibrinolytic activity in blood and nasal mucosa.

Laboratory assistant Magne Johnsen for valuable help with preparation of fibrinogen and help with the figures.

Laboratory assistants Maj Olausson Catherine Bergholtz, Barbro Christenson and Barbro Ljungdahl who helped me with the coagulation analyses.

Swedish Medical research Council for statistical treatments of the results, which has given me by Anders Oden, Fil.lic., Department of Mathematics, University of Goteborg.

Mr Norman Lewis, who has kindly revised my English.

This investigation was supported by grants from AB KABI, Stockholm, Sweden, Göteborgs Läkarsällskap Goteborg, Sweden and the Faculty of Medicine University of Göteborg, Sweden.

SUMMARY

Bleedings from the nose are experienced by many people In spite of this the incidence the cause and course of nose bleedings have been poorly investigated.

In the present investigation a randomly selected population sample of 410 subjects and 1 118 patients, who visited Ear Nose Throat doctors due to epistaxis, were studied.

In the population sample was noted that 60 per cent of the subjects had bled from the nose at least once in life but only 6 per cent had been treated for it by a doctor

Subjects who frequently have nose bleedings do not necessarily require professional treatment.

The nose bleeding started without any obvious reason in 65 per cent of the patients, in 28 5 per cent it was released by different traumas against the structures of the nasal cavities.

The bleeding source was localized on the nasal septum in 91 per cent of the patients less than 20 years and in 68 per cent of the patients more than 40 years old.

Distinct arterial bleedings were more frequent in patients more than 40 years old than in younger patients.

Histories of upper respiratory infections and intake of acetylsalicylic acid were more common in patients with epistaxis than in subjects in the population sample About 10 per cent of the subjects in the population sample had noted an association between upper respiratory infections and nose bleedings.

In the patients, but not in the control subjects, inflammatory reactions in nasal mucosa biopsies, taken from the side opposite to the bleeding side were seen

The frequency of histories of hypertension was not higher in out patients than in the population sample. A history of hypertension did not seem to predispose to habitual nose bleedings.

The distribution of different blood pressures was the same in the examined patients (some weeks after the actual bleeding) as in a population sample

Family histories of epistaxis were correlated to habitual nose bleeding but not to demonstrable defects in the hemostasis. Neither were habitual bleedings correlated to demonstrable defects.

In 41 per cent of the patients examined abnormal values in at least one of the routine tests of hemostasis were observed. The bleeding time was significantly longer in patients who had taken acetylsalicylic acid than in the other patients. All patients with normal platelet count and abnormal bleeding time had taken acetylsalicylic acid.

The measured hemoglobin values indicated that 43 per cent of the out patients and 73 per cent of the hospitalized patients were anemic.

Fibrinolytically active bacterial strains were found in 8 per cent of all examined patients, when they were bleeding.

The spontaneous fibrinolytic activity in euglobulin precipitate from plasma was significantly higher when the patients bled than some weeks later

The releasable fibrinolytic activity from the vessel wall after venous occlusion was significantly higher in the patients, one month after the bleeding episode than in the control subjects.

With a new micro method for determination of tissue plasminogen activator it was found that the total fibrinolytic activity in the nasal mucosa was significantly higher when the patients bled compared with one month later

In a double blind study with the antifibrinolytic drug tranexamic acid (Cyklokapron®) it was possible to demonstrate that recurrent bleedings were significantly less in number and severity when the patients were treated with Cyklokapron® compared with placebo. It was also observed that the hospitalisation time was significantly shorter when the patients were treated with Cyklokapron® instead of placebo

Aural Participation in Congenital Malformations of the Organism

BY

GEORGE KELEMEN M.D

From the Eccles Temporal Bone Laboratory of the Ear Research Institute,
and the School of Medicine, University of Southern California,
Los Angeles, California, USA

UPPSALA 1974

Introduction

Aural manifestations that present themselves, not independently but as part of a more or less high degree of abnormality of the entire organism, have been termed by Marx (1926) secondary manifestations. They represent partial phenomena of general abnormalities. As to their time-distribution, or periods of origin, the following so-called teratological termination points can be placed (1) the end of the organogenetic phase roughly at the end of the third gestational month (2) at delivery (3) during the post partum period without definite termination, when teratological influences may become manifest even at late phases of life.

Within all three periods, a number of cases were secured for further study with the aim to find, amid multiple malformations of the organism, aural participation—if any

Material and Methods

Opportunity for such study was offered in the substance of 54 cases with multiple malformations. Detailed clinical history autopsy protocol and sectional series of the temporal bones, of both sides, were extant. For the overwhelming majority the specimens were most obligingly released after autopsies at the Lying-In Hospital (pathologists Drs W Benirschke and S. G Driscoll), and the Children's Medical Center Hospital (pathologists Drs J M. Craig and G F Vawter) of the Harvard Medical School, Boston. Their cooperation, institutions and pathologists, are most heartily appreciated. The temporal bones were processed, after EDT (versene) decalcification, according to the usual celloidin method, sectioned, mostly in the horizontal plane and around 20 micra, stained with hematoxylin-eosin, Heidenhain-Mallory Bodian's, Gomori impregnation and, where warranted with auxiliary stains, and examined in direct and polarized light. Of these cases 26 originated from males 22 from females, in 6 the sex could not be ascertained. All three age groups, pre peri- and postnatal, were represented, in the following distribution

Period	No. of cases
Between 15 and 20 gestational weeks	4
Between 1 and 41 hours post partum	6
Between 3 days and 16 months post partum	35
Between 2 and 13 years of age	9

Four were stillborn craniotomy has been applied once, and one case carried the note neonatal death"

The ears turned out to be in the expected developmental stage and were without pathology in 21 cases (38.8%). It is regrettable that in the clinical history coming from departments without special interest in the condition of the hearing organ, no attention was paid to its functional history and data regarding hearing and vestibular function were lacking in patients of all ages.

Introduction

Aural manifestations that present themselves, not independently but as part of a more or less high degree of abnormality of the entire organism, have been termed by Marx (1926) secondary manifestations. They represent partial phenomena of general abnormalities. As to their time-distribution or periods of origin the following so-called teratological termination points can be placed (1) the end of the organogenetic phase roughly at the end of the third gestational month (2) at delivery· (3) during the post partum period without definite termination, when teratological influences may become manifest even at late phases of life.

Within all three periods, a number of cases were secured for further study with the aim to find, amid multiple malformations of the organism, aural participation—if any

Material and Methods

Opportunity for such study was offered in the substance of 54 cases with multiple malformations. Detailed clinical history autopsy protocol and sectional series of the temporal bones, of both sides, were extant. For the overwhelming majority the specimens were most obligingly released after autopsies at the Lying-In Hospital (pathologists Drs W Benirschke and S. G Driscoll), and the Children's Medical Center Hospital (pathologists Drs J M. Craig and G F Vawter) of the Harvard Medical School, Boston. Their cooperation, institutions and pathologists, are most heartily appreciated. The temporal bones were processed, after EDT (versene) decalcification, according to the usual celloidin method, sectioned, mostly in the horizontal plane and around 20 micra, stained with hematoxylin-eosin, Heidenhain-Mallory Bodian's, Gomori impregnation and, where warranted with auxiliary stains, and examined in direct and polarized light. Of these cases 26 originated from males, 22 from females in 6 the sex could not be ascertained. All three age groups, pre peri- and postnatal, were represented, in the following distribution

Period	No. of cases
Between 13 and 20 gestational weeks	4
Between 1 and 44 hours post partum	6
Between 3 days and 16 months post partum	35
Between 2 and 13 years of age	9

Four were stillborn craniotomy has been applied once and one case carried the note "neonatal death"

The ears turned out to be in the expected developmental stage and were without pathology in 21 cases (38.8%). It is regrettable that in the clinical history coming from departments without special interest in the condition of the hearing organ, no attention was paid to its functional history and data regarding hearing and vestibular function were lacking in patients of all ages.

Findings

Table I demonstrates, in each case, separately the general malformation opposite the findings in the ear normal or pathological

Table II groups together the different organ systems opposite the most frequently found aural pathology Negative (normal) ear findings are included and these show whether the general malformations extended or failed to extend to the hearing organ

Table III includes some of the syndromes most frequently associated with changes in the ear A number of conditions do not fit into the single organ groups and are tabulated separately under Varia" (Table IV) By juxtaposition of the ear pathology if any to the organ group with general malformations, connection between the two units was made more con spicuous.

Among the units of ear pathology the follow ing were the most frequent Otitis neonatorum (12 cases) otitis media suppurativa in more advanced age groups but here it was not possible to be certain whether the start should be placed in the immediate postnatal period Incipient cholesteatoma (3 cases) was restricted to the immediate vicinity of the tympanic membrane ("central cholesteatom Schwarz, 1963) polyp formation was seen in several cases. Gaucher cells, characteristic for lipoidoses, were seen twice. Bilateral stapedial arteries were present once, with another case in the incipient stage the vessel, originating from the internal carotid wound around the bottom of the tympanic cavity but failed to reach the stapedial region (Kelemen 1958) Malformed stapes was seen three times, always unilateral and once of the type of the étrier coudé (Ombrédanne, 1954) Malformed cochlea was present once Hydrocephalus was observed seven times with and twice without ear pathology (Niccoli Vallesi (1958) reporting on a part of this material) No Mondini defect was seen although its appearance is said to be frequent in cases of widespread, general malformations (Illum 1972) Paget-like islands in the bony structure of the inner ear capsule were present several times (cf Kelemen (1970), observed and described in detail).

Anencephaly the most frequent of the malformations of the head was lacking from this material The statement of Adair & Potter (1949) according to which malformations are commonly observed more frequently in the skull and its contents that in other parts of the body was corroborated The only runner up group, was that showing skeletal abnormalities, possibly because deformities of this group are easily observed and will hardly be overlooked

Single ear deformities although recorded in the tables, have been given only a few remarks here warranted for special reasons it was deemed unnecessary to add to the many detailed descriptions extant Of these only a few should be mentioned Marx (1926) Nager & de Reynier (1948) Altmann (1957 and 1965) Schwarz & Becker (1964) Silcox (1967), Warkany (1971) Jorgensen (1972) Terrahe (1972) Sando (1971) presented a series of congenital anomalies of the middle ear subgrouped according to the presence of associated anomalies of the latter however it was not yet possible to compile a comprehensive list because of the small number of histopathological reports.

It has been mentioned that a considerable percentage of the hearing organs was found to be in adequate developmental stage and without pathology in organisms that show a long list of abnormalities in many organs. To these might be added cases in which in what has been termed above, the "third stage pathology had possibly already originated in the second, or perinatal period An otitis media may develop in a very short time, even with polyps, cysts, organizations, exostoses, soon after birth and without strict connection with the neonatus otitis. The latter was declared by Aschoff (1897) to be a foreign body otitis, built around fetal

material Thalhammer (1967) stated that the fetus starts to swallow amniotic material as early as the 16th week. Timing difficulties show up in different periods, and considerable caution should be exerted before placing the origin of any pathological sign at a precise point of the teratological timetable

It seems that consensus puts the start of inflammatory manifestations from the fourth fetal month. At this time the inner ear development is already far advanced Dating of ear pathology far back is a hard task not duly emphasized.

The histological work was done at the laboratories of 1) the 2. Surgical Clinic, University of Budapest, Hungary 2) the Mosher laboratory of the Massachusetts Eye and Ear Infirmary Department of Otolaryngology Harvard University Boston, Mass. 3) The Eccles Temporal Bone Laboratory of the Ear Research Institute School of Medicine, University of Southern California, Los Angeles, California.

Discussion

Congenital deformities have always evoked interest Warkany (1963) mentioned that malformations of the ear were already engraved in the tablets of ancient Babylonic scribes, maybe 4000 years ago The period between 100 A.D. and 1500 A.D has been termed by House (1962) the dark age of otology" Cook (1838) complained that "from the earliest ages to the present time" pathology of the ear has been almost wholly neglected. But when the early textbooks of otology were prepared, abnormalities were given due attention Pilcher (1838) in his Essay offered 22 pages to development and malformations of the ear as introduction to the treatment of the diseases of the latter However he explained that knowledge of these malformations was capable of application in the praxis only to a slight extent On the other hand, he found it easy to trace in these malformations a correspondence to permanent structures of inferior classes" meaning lower animals. Politzer himself (1926), almost a century later declared operative interference in cases of atresia of the external meatus to be useless and further more irrational and dangerous. Since his time rehabilitation of deformities has advanced most decisively as has the knowledge of malformations and their significance in the hearing organs of animals (Kelemen, in press).

Bauer (1945) emphasized that a constitutional biological inferiority of the auditory apparatus occurs in certain strains.

The endless amount of work around the topic has been characterized by Apgar (1963), who said that while in the past few years, attention and interest has been focused on birth defects as never before, otolaryngology has taken its appropriate part in clarification. She pointed to the desirability to put aural deformities into the framework of general malformation of the organism. Nager & de Reynier (1948) complained about the lack of reports on changes of the hearing organ in cases of congenital head malformations. While aural malformations as mentioned by Livingstone & Delahunty (1968) may form an integral part of syndromes such as Treacher-Collins or Wardenburg, rare conditions of congenital deformities are lacking in many clinical descriptions even when recorded as an associated anomaly Berberich (1959 1960) complained that in the enormous literature on birth injuries otologic aspects received comparatively little attention. He tried to integrate ear findings with those in a group of patients admitted for a great variety of conditions, besides birth injury as hydrocephalus, congenital syphilis, chorea, encephalitis, various infectious diseases and nutritional disorders.

The difficulty of enrolling abnormal conditions in one or the other of the three main teratological

periods has been mentioned in several sources. Livingstone (1965) considered it very difficult to know the exact age of the fetus or the date when the damage occurred Ormerod (1960) in his studies on the pathological basis of congenital deafness, found it especially hard to evaluate the date of happenings in the second period between organogenesis and birth Warkany (1971) found the borderlines vague between congenital malformations and congenital microscopic or functional disturbances Lénárt found it not easy to enroll the special case into the first (embryonic) as against the second *(fetal)* teratogenetic period Bramley (1963) declared it difficult to enroll a progressive hearing loss appearing at any time, at any period Kanizsai (1961) thought that as defects can be attributed to internal or external causes, they can be enrolled into any period of organic development. Benirschke (1967) called attention to the possible interaction of viruses with the fetus as a cause of latent disease multiplicity and ubiquity would find explanation along this line. Luchsinger (1970) stressed the necessity of placing inner ear disturbances as participants in multiple malformations Arnold (1970) emphasized the importance of being aware that congenital and acquired malformations may cause hereditary congenital connatal, or early acquired types of functional disorders.

It may help to accept the chronological classification of Goodhill (1971) which recognizes only hereditary and acquired lesions.

As to the frequency of aural participation in general multiple deformities—which is our special interest in this presentation—few data can be found these however are not grouped in a systematic way and differ widely among themselves In his embryological collection comprising 500 pairs of ears, Bollobás (1972) found 18 pairs with developmental anomalies. Crifó & Benincori (1972) estimated that one third of the *general malformations extends to the realm of* the otolaryngologist—a proportion borne out by the here reported series. Fishbein (1963) stated that practically every baby had some minor defect of one kind or another but that most of these already had been outgrown or overcome by the time the child was one year old In other communications single parts of the hearing organ were interpreted *relative* to other parts of this organ as mentioned above deformities can be restricted to single parts of the ear Takahashi & Tsutsumi (1958), in a very detailed analysis, presented microtia against a number of concomitant intraaural conditions. Livingstone (1965) emphasized that, although the outer and middle are deformed, the inner *ear may remain unaffected Comparative pathology too offers many examples of this nature*

Summary

The aim of this presentation was to tabulate participation of the organ of hearing in multiple malformations of the entire organism 54 cases were analyzed with clinical history autopsy protocol and sectional series of the temporal bones extant About one-third showed no ear pathology with some added where abnormalities were restricted to parts of the ear other parts *remaining intact In the text* separate description of single forms of pathology was limited to a few findings, as enumeration of similar signs *can be found* (1) in the tables and (2) in numerous competent publications

Lack of participation of the ear in general deformities in a comparatively *high percentage* was unexpected and did not corroborate the—scarce—data of previous publications, from which, however temporal bone histopathology was mostly absent available here in all cases

Difficulty to assign the origin of a particular defect to a precise point of the teratological timetable, in many cases, was accentuated

Zusammenfassung

Die Beteiligung des Gehörorgans an multiplen Missbildungen des Gesamtorganismus wurde dargestellt. 54 Fälle mit klinischer Geschichte, Autopsieprotokoll und Schnittserien der Felsenbeine standen zur Verfügung. Ungefähr ein Drittel der letzteren *zeigte nichts Krankhaftes*, einschliesslich einigen, wo Abnormales auf einen Teil des Ohres beschränkt war. Die Beschreibung von einzelnen Formen der Pathologie wurde begrenzt, da detaillierte Informationen in den Beilagen und in zahlreichen kompetenten Mitteilungen vorliegen.

Die in einem verhältnismässig hohen Prozentsatz minimale Beteiligung des Ohres an allgemeinen Missbildungen war unerwartet und steht im Gegensatz zu Daten früherer Mitteilungen, in denen jedoch keine Felsenbeinpathologie zur Verfügung stand.

Auf die Schwierigkeit, einzelne Defekte einem präzisen Punkt der teratologischen Chronologie zuzuschreiben, wurde hingewiesen.

		Autopsy	Aural findings
1 M	13½ w (gest.)	Incomplete fissuring of L lung; bilateral agenesis of kidneys & ureters, oligohydramnios; maternal diabetes mellitus	Normal
2 ?	17 w (abortion)	Cystic hygroma of neck, lymphangiectasis of lung; cerebellar anomalies, polycystic kidney	Hemorrhages in endolymph of semicircular canals, around cristae, tip of cochlea
3. M	19 w (interruption)	Maternal heart disease	Normal
4. M	20 w (interruption)	Maternal nephrosis	Adequate developmental stage
5 F	34 w (premature)	Meningo-encephalocele, occipital microcephaly; microgyria, hypoplasia brain stem, agenesis olfactory bulbs & optic nerves, bilat. microophthalmia, multifocal cerebral calcifications; harelip, cleft palate, persistent ostium primum, persistent L duct of Cuvier; stenosis of aortic ring, cleft mitral valve, left ventricular hypertrophy; accessory spleens, sclerosis & bile duct proliferation, periportal regions, liver; polycystic kidneys, uterus didelphys, clubfoot, club hand bilat., bilat. talipes equinovarus, widely separated sutures, recent hemorrhage lat. ventricle	Bilat. persistent, stapedial artery
6. ?	Stillborn	Polycystic kidney	Normal
7 F	Stillborn	Spina bifida, hydrocephalus	R. severe malformation of cochlea, only 1½ turns; no Reissner's; tectorial agglutinated. Corti flat stria normal, malformed stapes; L Rosenthal canal mostly empty
8 M	Stillborn	Polycystic kidney, penile agenesis, absence of scrotum, cleft palate, harelip; webbing of neck; absence of tongue; polydactylism, situs inversus, cirrhosis of liver; hypoplasia of lungs; accessory spleen; hypoplasia of stomach, undescended testes, hydrocephalus, agenesis of corpus callosum; obliteration of aqueduct, club feet	L.s. exostosis inner ac. meatus, both in vestibular nerve; exostosis of posterior wall of niche of round window
9 M	Stillborn	Hydrocephalus, necrosis of liver & kidney; ? toxoplasmosis	Normal
10 M	1 h	Cerebral congestion, edema, cephalopelvic disproportion, cephalohematoma, hydronephrosis, hydroureter; parathyroid hyperplasia or adenoma, premature involution of adrenal fetal cortex, maternal pseudohypoparathyroidism	Organizing cushions in both windows; obturator foramen; central space in mesenchyme remnants of stapedial artery; calcification in vascular stria, basal turn
11 F	1 h 35 min	Premature, 25 cm CR, polycystic kidney; hypoplasia of lung; encephalocele, occipital hydrocephalus, peculiar liver & adrenals; club feet; bicornate uterus, ... ide fontanelles	Carotis, partial course of stapedial artery; excavation of cochlear capsule by carotid canal

Table 1

		Autopsy	Aural findings
1 M	13½ w (gest.)	Incomplete fissuring of l. lung; bilateral agenesis of kidneys & ureters, oligohydramnios, maternal diabetes mellitus	Normal
2 ?	17 w (abortion)	Cystic hygroma of neck, lymphangiectasis of lung; cerebellar anomalies, polycystic kidney	Hemorrhages in endolymph of semicircular canals, around cristae, tip of cochlea
3 M	19 w (interruption)	Maternal heart disease	Normal
4 M	20 w (interruption)	Maternal nephrosis	Adequate developmental stage
5 F	34 w (premature)	Meningo-encephalocele, occipital microcephaly; macrogyria, hypoplasia brain stem, agenesis olfactory bulbs & optic nerves; bilat. microphthalmia, multifocal cerebral calcifications, harelip, cleft palate; persistent ostium primum, persistent l. duct of Cuvier; stenosis of aortic ring; cleft mitral valve, left ventricular hypertrophy; accessory spleens, sclerosis & bile duct proliferation, periportal regions, liver; polycystic kidneys, uterus didelphys, clubfoot, club hand bilat., bilat. talipes equinovarus, widely separated sutures, recent hemorrhage lat. ventricle	Bilat. persistent, stapedial artery
6 ?	Stillborn	Polycystic kidney	Normal
7 F	Stillborn	Spina bifida, hydrocephalus	R. severe malformation of cochlea, only 1½ turns, no Reissner's, tectorial agglutinated. Corti flat, stria normal, malformed stapes, l. Rosenthal canal mostly empty
8 M	Stillborn	Polycystic kidney, penile agenesis, absence of scrotum; cleft palate, harelip; webbing of neck, absence of tongue; polydactylism, situs inversus; cirrhosis of liver; hypoplasia of lungs, accessory spleen, hypoplasia of stomach, undescended testes, hydrocephalus; agenesis of corpus callosum; obliteration of aqueduct; club feet	L.s. exostosis inner ac. meatus, high in vestibular nerve; exostosis of posterior wall of niche of round window
9 M	Stillborn	Hydrocephalus, necrosis of liver & kidney; ? toxoplasmosis	Normal
10 M	1 h	Cerebral congestion, edema, cephalopelvic disproportion, cephalohematoma, hydronephrosis, hydroureter; parathyroid hyperplasia or adenoma, premature involution of adrenal fetal cortex, maternal pseudohypoparathyroidism	Organizing cushions in both windows, obturator foramen, central space in mesenchyme resembling of stapedial artery; calcification in vascular stria, basal turn
11 F	1 h 39 min	Premature, 25 cm CR, polycystic kidney; hypoplasia of lung; encephalocele, occipital, hydrocephalus, peculiar liver & adrenals, club feet; bicornuate uterus, wide fontanelles	Carotis; partial course of stapedial artery; excavation of cochlear capsule by carotid canal

		Autopsy	Aural findings
12. M	5 h	Hydrocephalus obstruction of aqueduct intussusception ileum	Int. sulcus, transudate one side
13 F	7 h	Cebocephaly microcephaly (arhinencephaly Kundrat) single imperforate central nostril palatoschisis, central cranial approximation of sutures prematurity 2 100 gr 28 cm CR	Hemorrhages inner meatus & subarach. fossa
14 F	15 h	Extreme prematurity immaturity severe degree pus in GI tract (? from infected amniotic sac)	Early reabsorption of mesenchyme (more particular considering extreme prematurity)
15 F	44 h	Maternal polio interventricular & subarachnoidal hemorrhage massive partial involution of thymus, hypoplasia of all organs immaturity of kidneys, intestines, brain lung	Normal
16. F	? d.	Microcephaly cong. heart disease cyanotic type dextrocardia coarctation of aorta septal defect choanal atresia hemangioma of nose umbilical hernia	Round window hyaline mass
17 M	3 d	Cong. heart disease r ventricular hypertrophy & dilatation l. ventricular hypertrophy hypoproteinemia central nervous system anomalies bilateral corneal opacities, pitting edema of extremities	Lacy bone, reminiscent of Paget s disease, in inner ear
18 M	3 d.	Encephalocele hypoplasia of cerebellum anomalous midbrain shallow post. fossa upward deviation of nerve roots cong. dislocation of hips, bilat. talipes equinovarus fracture of skull large defect, occipital bone (difficult delivery face presentation) large encephalocele	Neonatus otitis media & interna, serofibrinous & suppurative, engorgement, extravasates
19 F	3 d.	Cong. heart disease, interventricular septaldefect overriding aorta, bicuspid, pulmonary valve hypoplasia of lungs Meckel diverticulum accessory spleen hematoma of thyroid prolapse of vaginal mucosa with Gortner duct remnant anomalous growth of cerebellar region multiple hemorrhages in brain cortex, thalamus, cerebellum immaturity of viscera	Hypoplasia of right internal ear otherwise normal ear
20. F	3½ d	Mongolism hydrothorax, bilat club feet fenestration of cups of aortic valve mural thrombus in cardiac ventricle	R. normal left serous labyrinthitis blood in cochlea
21 M	4 d.	Tracheo-esophageal fistula (type C Gross) patent ductus arteriosus agenesis l kidney & ureter single umbilical artery multiple anomalies of vertebral column, incl. hemivertebrae anomalies of circle of W ll s mongolism (paternal ricketts)	Cochlear aqueduct dilatation remnant of stap artery (straightened out) carotid canal deep indentation into cochlear capsule malleus inserted in cyst in tympanic membrane, source of noninflammatory cholesteatoma
22. M	7 d	Prematurity (37 5 cm, 3 lbs) clouding of cornea cleft palate abnormal position of vocal cords esophageal atresia absence of lung fissure hypoplasia of lungs right aortic arch tetralogy of Fallot hypoplasia of pulmonary artery	Malformation of pinna absence of ext. meatus r malform. stapes (single crus, bulky) ext. canal closed by bony plate,

		Autopsy	Aural findings
		bicuspid stenotic valve· membranous inter ventricular septal defect overriding of aorta, malrotation of intestines annular pancreas stenosis of duodenum, absence of celiac artery· stenosis of rectum, dilatation of descending colon & sigmoid, hypoplasia of kidneys, cryptorchismus· clubbing of hands; absence of thumbs absence of radii hydrocephalus, internal	spaces into fibrous mass, L stapes fracture· malleus long process did not develop
23. F	9 d	Renal hypoplasia micrognathia, bicornate uterus skeletal anomalies	R. partial ectasia of tympanic scala, middle turn
4. F	13 d.	Central nervous system absence of corpus callosum, hypoplasia of cerebellum, hypoplasia of temporal and parietal lobes bilat. coloboma ant. displacement of anus, bilobed r. lung; double arterial supply of kidney· hyperextendibility of joints absence of elastic tissue of skin cardiomegaly· hepatomegaly· nephromegaly	Normal
25 M	19 d	Hydrocephalus; hypoplasia of olfactory organ, of optic nerve, of IIth nerve; absence of septum pellucidum & corpus callosum hypoplasia of cerebellum, erosion of ant. clinoid process, malformation of cerebral fossae· hydronephrosis, pulmonary atelectasis	Erosion of petrous bone· neonatus otitis media, probably intrauterine origin, dilatation of all perilymphatic spaces, incl. cochlear aqueduct some extravasation middle & int. ear (forceps?)
26 F	21 d.	Omphalocele· cong. heart disease, cyanotic; fenestrated valve foramen ovale patent ductus arteriosus dilated atrium, dilated L ventricle common mesentery for small & large intestines spina bifida occulta, sacrum, esophageal hiatal defect	Neonatus otitis purulenta, left, rosary row of cysts in mucous membrane
27 F	24 d.	Pulmonary artery coming off r. pulmonary artery and crossing the midline to the left between trachea and esophagus, cardiomegaly· obstructive pleuritis, bilat., diaphragmatic muscle strands attached to lat. chest wall· fusion of right ribs, hemivertebrae on level of 5th & 7th cervical vertebral bodies, dorsal scoliosis	R. hypoplastic external ear auditory canal not patent, otherwise normal (in spite of breech)
28 M	25 d.	Congenital toxoplasmosis; calcification of cerebral cortex internal hydrocephalus, hepatomegaly· splenomegaly· interstitial pneumonia, pulmonary edema, solitary cyst of liver· hilar lymphadenopathy· extensive dilatation of ventricular system	Neonatus otitis media, organizing bands
29 F	30 d	Micrognathia microphthalmia, microcephaly· bulb nose· narrow arched palate short neck, flattened cervical vertebrae; low hair line posteriorly dislocation L hip· L talipes calcaneovarus, overweight brain temporal hamartoma, asymmetry & L sides of post. fossa anomalous circle of Willis, cong. heart disease: patent for ovale, ventricular septal defect; biventricular hypertrophy· endocardial sclerosis, coarctation of aorta patent ductus arteriosus dilated pulmonary arteries; Meckel diverticulum, accessory diverticulum, non-attachment of mesentery· bands from duodenum to liver & from ileum to cecum, ovarian cyst, simple diaphragmatic hernia congested liver	R. Paget's-like bone in inner ear capsule, otherwise normal

		Autopsy	Aural findings
30 M	32 d.	Imperforate anus pulmonary hyaline disease cyanotic heart disease microcephaly lacunar skull, 3 fontanelles mongolism intestinal malrotation congenital heart hypoplasia l. atrium, l ventricle, aorta endocardial sclerosis, l atrium premature closure of foramen ovale patent ductus arteriosus r ventricular hypertrophy hypoplasia, left kidney	Normal
31 M	39 d.	Pierre-Robin prematurity cong. heart disease ventricular *septal defect hypertrophic r* ventricle small mandible recessing of chin high arched palate bicuspid pulmonary valve bicuspid aortic valve widely open ductus arteriosus *defect of diaphragm malformation* of spleen horseshoe kidneys with multiple renal arteries r inguinal hernia single umbilical artery	Low set ear malformed *pinnae otherwise ear* normal
32. F	6 w	Hysterotomy bulbar polio	Normal
33 F	4 mo.	Hydranencephaly adrenal atrophy hepatosplenomegaly thymic involution cardiomegaly accessory spleen signs of old meningitis cerebral hemispheres almost completely replaced by membranous sacs filled with serous spinal fluid & some rudimentary cortical tissue	Neonatus otitis, bilat. (sero-fibrinous) sign of central irritation cuffing of vessels in thick polypous tympanic membrane (basal hydrocephalus?)
34 M	7 w	Communicating hydrocephalus subarachnoid-ureteral shunt cerebral edema	Neonatus (intrauterine?) otitis media signs of organization cholesteatoma-sac formation, upper half of tympanic membrane left side
35 M	7 w	Microcephaly cong. lues ? toxoplasmosis hydranencephaly with microcephalus, cong. defect in occipital bone hepatomegaly generalized icterus renal disease with bile necrosis? adrenal hypoplasia undescended r testicle partially differentiated eye	L.s. transudate in several *locations, middle ear* some organization
36. ?	?	Microtia	Normal
37 F	7½ w	Multiple anomalies hepatitis, neonatal	Reissner pressed to the organ *of* Corti, *r* side in the vestibule, perilymphatic edema
38 M	3 mo	Infantile muscular atrophy *(Werdnig-Hoffmann)* involvement of trunk and limb muscles secondary to anterior horn degeneration in spinal cord without apparent tract disease	Normal
39 M	3½ mo	Treacher-Collins syndrome coloboma *palpebrae* hypertelorism micrognathia glossoptosis hypoplasia of maxilla & zygomatic arch cleft palate, posteriorly obstruction l nasal passage left choanal atresia fenestration *of falx* cerebri *& tentorium* cerebelli pectus excavatum atelectasis of lungs, bilat. atrophy of thymus hemorrhages, focal, submucosal, ileum and colon	Hypoplasia of pinna absence of ext. aud. meatus agenesis *of* ossicles r stapes single crus from center *of* foot plate large dehiscence of facial canal incudostapedial articulation absent

		Autopsy	Aural findings
40. M	4 mo.	Clenched fist, flexed great toes, deformed chest; fibrous defect of clavicle; short sternum diastasis recti, pancreatic ectopia, Meckel diverticulum, underdeveloped olfactory bulb & cribriform plate; partial defect of diaphragm, incomplete rotation of kidney, double renal arteries, urachal cyst, partial failure of mesentery; accessory pulmonary fissure; hypoplasia of iliac arteries, delayed & irregular development of skeletal muscles, cong. heart disease: ventricular septal defect, hypoplasia of mitral valve ring; venous hypertrophy; coarctation, patent ductus arteriosus, small patent foramen ovale, high arched palate; high thymus, persistent l. sup. vena cava, bilat. azygos venous system	Malformed middle ear (gross); serous labyrinthitis, chronic otitis media, extravasates, inner ear: l.s. lymphatic edema around utricle; malformed stapes *single crus, inset center* of footplate
41 F	3 w	Prematurity, 23 weeks gestation intrauterine *fetal death due to placental degeneration* hemorrhages in many organs; breech, maternal death 6 hours after delivery; Asiatic influenza pharynx washings, large amount of Asiatic flu strain	Intrauterine otitis media, serous-sanguinolent, deep pockets around malleus formed by desquamated lamellae, potential source of cholesteatoma (sanguinous character common in influenza otitis)
42 F	11 mo.	Marfan syndrome: small cranium, coronary synostosis, loose skin, poor muscular development, bilat. talipes equinovarus, wrist drop bilat. dislocation of hips, arthrogryposis, high arched palate; arachnodactyly; lenticular dentures; delayed dentition, osteochondrodystrophy; Marfan heart & pulmonary disease; underweight brain, undernourishment, fatty liver, hypoplasia of pancreatic islets	R.s. saccus endolymphaticus dilation with edematous papillae, otherwise normal ear
43 F	16 mo	Ventricular taps & shunts, ... revisions, non-communicating hydrocephalus, cyst of 4 ventricle; absent inf. vermis, (Dandy-Walker) platybasia, pituitary cyst; ... l. kidney cortical scarring of ... kidney secondary to healed pyelonephritis, cachexia, anemia, dehydration, multiple gastric ulcerations, minimal gastric hemorrhage, patent ductus arteriosus, cardiomegaly, pulmonary artery hypertrophy; r. ventricular hypertrophy; atelectasis posterior segment of l. lobe; absence of mesenteric attachment	Normal
44 F	1 y	Cerebral dysgenesis, atrophy with microcephaly; neonatal myoclonus; underdevelopment	Normal gazed in direction of rotation, *without* nystagmus
45 F	1 y	Cerebral dysgenesis, atrophy, microcephaly underdevelopment	*Side?* Rosenthal canal empty at base
46 F	2 y	Nephritis, multiple anomalies	Normal
47 F	2 y	Microcephaly, severe cerebral & cerebellar atrophy (? rubella)	L.s. severe supp. otitis media, abscess *between* layers of tympanic membrane

		Autopsy	Aural findings
48. M	½ y	Cong. heart disease, cyanotic, tetralogy of Fallot hypoplastic pulmonary arteries bicuspid pulmonary valve valvular stenosis, pulmonary dextroposition of aorta hypertrophy of r ventricle ventricular septal defect pulmonary stenosis or atresia	L.s. chron. otitis media, advanced organization, beginning of cholesteatom formation large extravasates in lumen of middle ear mucous membrane high polypous, with dense *cellular infiltration*, many resorption buds, windows obliterated, stapes to complete immobilization, large polyp from tubal corner extravasates in carotid canal inner ear intact, end organs in excellent preservation (deafness at admission at 25 mos. ? rubella)
49 M	3 y	Hurler s syndrome (gargoylism) involvement of brain mitral valve, arteries (aorta, coronaries, sup mesenteric, renal iliac) bladder eyes *(proptosis) subarachnoid cyst overlying* pituitary fossa skeletal changes affecting spinal column & skull short teeth, dysodontia splenomegaly (hyperplasia of white pulp), *hypertrophy of lymph nodes, generalized ridge* around neck of urinary bladder pulmonary atelectasis, congestion & edema, umbilical hernia mild hirsutism clubbing of fingers, *external hemorrhoids*	R.s. otitis media, massive organization, blocking of windows, abnormal ossification *focus of Gaucher* cells in cochlear capsule, in tegmen large cartilaginous island, with small bone particles *with lamellary* structure, without osteoblasts inf wall of tympanic cavity cartilaginous space enclosing exostosis on slender pedicle with central marrow space and cartilaginous cap at distal extremity cochlear capsule lower turn large resorption focus penetrating all layers except endosteal containing, on a fibrous basis, large cells with peripherally spaced nuclei (? Gaucher) no words ever used
50. M	3 y 7 mo.	Ac. poliomyelitis, ac. toxic reaction of lymphoid tissue marked involvement of midbrain, basal ganglia, pons, med oblongata high cervical cord involvement lesser degree of cerebral cortex, cerebellum, *lower spinal cord*	Normal
51 M	4 y	Hurler s syndrome hepatomegaly hydrocephalus, coronary artery involvement	R.s. chron. otitis media persistence of mesenchymal filling of middle ear blocking both windows *signs of abnormal ossification* fibrous island in mastoid two small osteomas in round window niche calcification n stria vascularis near round window
52. M	7 y 10 mo.	Riley-Day syndrome scaly dry skin of chest alopecia temporal region	Both sides, vestibular aqueduct & saccus dilatation

		Autopsy	Aural findings
3. F	8 y 3 mo.	Ac. leukemia with hemorrh. diathesis, gastrointestinal hemorrhage; hepatosplenomegaly; renomegaly with frank hemorrhage into calyces, slight l. ventricular hypertrophy with focal endocardial hemorrhage; generalized petechiae and ecchymoses on epithelial surfaces	R.a. extravasates in endo- and perilymph spaces in vestibule; systolic bruit over mastoid at age 8 years complaints of "hearing things" diplopia, spots in front of right eye
4. M	13 y	Cong. heart disease: atrioseptal defect, cardiomegaly l. ventricular hypertrophy & dilatation, l. pulmonary edema & congestion, hemothorax, hepatic cirrhosis; splenomegaly: renal ischemia, bilat. hypoplastic testes, hypoplastic penis: hypospadias, lipoid depletion of adrenals, mental retardation	Cyst forming med. wall of int. ac. meatus

Table II

	Aural pathology
Circulation	
Cardiomegaly	B.s. neonatus otitis
Cardiomegaly atrial septal defect	0
Cardiomegaly patent duct. arteriosus, r ventricular & pulm. art. hypertrophy	
Cardiomegaly r ventr hypertrophy & dilat.	0
Cardiomegaly patent duct arteriosus, r ventr & pulmonary *artery hypertrophy*	Cyst in internal meatus
Patent ductus arteriosus	Cochlear duct dilatation incip. choleath. in tympanic membrane
Patent ductus arteriosus, fenestrated for ovale, dilat. r atrium, l ventricle	Otitis media purul. ? neonat. (21 days)
Patent ductus arteriosus, coarctation of aorta, ventral septal defect, patent for ovale, hypoplasia of mitral valve ring	R.s. serous labyrinthitis, l.s. malformed stapes
Patent ductus arteriosus, coarctation of aorta, patent for ovale, ventricular septal defect, endocardial sclerosis	Paget-like islands in inner ear
Ventricular septal defect, hypertrophy r ventricle	0
R. ventr hypertr & dilatation, l. ventr hypertrophy focal endocard., hemorrhages	Paget-like islands in inner ear extravasates in endo- & perilymph spaces
Fenestration of cups of aortic valve, mural thrombus in cardiac ventricle	L.s. serous labyrinthitis
Interventricular septal defect, overriding aorta	0
Persistent ostium primum, persistent l. duct. of Cuvier stenosis of aortic ring, cleft mitral valve, l ventricular hypertrophy	Bilat. persistent stapedial artery
Dextrocardia, coarctation of aorta, septal defect	*Hyalin mass in round window*
Involvement of mitral valve, coronaries	R.s. otitis media (3 years)
Cyanotic heart disease	0
Marfan heart & pulmonary disease	Saccus endolymph. dilatation
Hurler coronary artery involvement	*Chronic otitis media (4 years)* b.s. ca. 60 db hearing loss, middle range
Fallot tetralogy	Malformed stapes & malleus
Fallot tetralogy (rubella) Maternal heart disease	L.s. chron. polypous otitis media 0
CNS	
Cerebral dysgenesis and atrophy microcephaly	Rosenthal canal empty
Microcephaly cong. defect of occipital lobe	Transudates, organizations
Microcephaly	Otitis med. supp.
Microcephaly 3 fontanelles, mongolism	0
Microcephaly overweight brain, tectorial hematoma, inequity r & l. post. fossa, anomalous circle of Willis	Low-set auricle, Paget-like islands in inner ear capsule
Microcephaly microgyria, hypoplasia of brain stem, shallow post. fossa, agenesis of olfactory bulb & optic nerves, microophthalmia, multifocal cerebral calcifications	Bilateral persistent stapedial artery
Microcephaly cebocephaly arhinencephaly Kundrat, cranial approximation of sutures	Hemorrhages int. meatus & subarcuate fossa
Absence of corpus callosum, hypoplasia of cerebellum, hypoplasia temporal & parietal bones	0
Microgyria	Ectasia tymp. scala, middle turn
Underweight brain, coronary synostosis	*Saccus endolymph. dilatation*
Occipital encephalocele	Otitis media & int. suppuration
Occipital encephalocele, hypoplasia of cerebellum, anomalous midbrain, shallow post. fossa, upward deviation of nerve roots	
Cerebral edema	Otitis media & int. cholest. sac cyst in tympanic membrane
Cerebral edema, congestion, cephalhematoma	Organization, both windows, calcification in stria
Calcification, cerebral cortex	Otitis media neonat.
Degeneration anterior horn, spinal cord	Catarrhal otitis media
Hypoplasia of olfactory organ, 5th nerve absence of septum pellucidum & corpus callosum, hypoplasia of cerebellum	Otitis media neonat.
"Cerebellar anomalies"	Blood in vestibule & semicirc canals
"Central nervous system anomalies"	Paget-like island in inner ear capsule
Anomalous growth of cerebellum	Hypoplasia, right ear

	Aural pathology
"Involvement of brain	Anomalies of cochlear capsule, otitis media supp.
Platybasia, Dandy-Walker	0
Pierre-Robin	Low set ear malformed pinnae
Spina bifida	Malformed cochlea
Erosion, ant. clinoid process, of petrous bone, malformation of cerebral fossae	Otitis media neonat.
Mongolism, rickets in father	Cochlear aqueduct dilatation, cyst in tympanic membrane
Mental retardation (13 years)	Cyst, inner acoust. meatus
Poliomyelitis ant., interventricular & subarachnoid hemorrhages	0
Polioencephalitis	0
Maternal bulbar polio	0
Maternal acute polioencephalomyelitis	0
Congenital defect of occipital bones	Catarrhal otitis med., organizations
Signs of old meningitis	Otitis media neonat.
Lungs	
Hypoplasia of lungs	Incipient stapedial artery
Hypoplasia of lungs	Exostosis in int. ac. meatus exostosis in niche of round window
Hypoplasia of lungs, absence of lung fissure	Malformed stapes
Bilobed right lung	0
Atelectasis of lungs	Malformed stapes
Atelectasis of lungs	Ot. med. neonat.
Atelectasis of lungs, congestion, edema (Hurler)	R. otitis media
Pulmon. edema, congestion, hemothorax	*Cyst*, int. acoustic meatus
Hydrothorax, bilat.	Serous labyrinthitis
Pulmonary hyaline disease	0
Intestines	
Umbilical hernia	Hyalin mass at round window niche
Diaphragmatic hernia	0
Inguinal hernia	0
R. inguinal artery	0
Immaturity of viscera	Hypoplasia r. ext. ear
Immaturity of viscera	0
Situs inversus, hypoplasia of stomach	Exostosis inner meatus, exostosis niche of round window
Malrotation of intestines, annular pancreas, stenosis of duodenum	Malformed stapes
Intussusception, ileum	Scattered transudates in middle ear
Common mesentery for small & large intestines	Otitis purulenta neonat.
Celiac artery absence	Malformed stapes
Meckel diverticulum, non-attachment of mesentery bands from duodenum to liver to ileum, to cecum, diaphragmatic hernia	Paget-like islands in inner ear capsule
Meckel diverticulum, pancreatic ectopia, diastasis recti, partial failure of mesentery hypoplasia iliac arteries	R. serous labyrinthitis, L malformed stapes
Defect of diaphragm	0
Gastrointestinal hemorrhages	Many extra stapes
Multiple gastric ulceration, gastric hemorrhage, absence of mesenteric attachments	0
Hemorrhages, submucous in ileum, colon	Malformed stapes
Pancreatic ectopia	Serous labyrinthitis, malformed stapes
Displacement of anus	0
Single umbilical artery	0
Single umbilical artery	0
Spleen	
Splenomegaly (hyperplasia of white pulp)	Otitis med.
Splenomegaly (hyperplasia of white pulp)	Cyst, inner acoust. meatus
Hepatosplenomegaly	Otitis media neonat.
Accessory spleen	Exostosis inner meatus, exostosis niche of round window
Accessory spleen	Hypoplasia external ear
Malformation of spleen	0
"Hypoplasia of all organs	0

Cardiomegaly	B.s. neonatus otitis
Cardiomegaly atrial septal defect	0
Cardiomegaly patent duct. arteriosus, r. ventricular & pulm. art. hypertrophy	
Cardiomegaly r. ventr. hypertrophy & dilat.	0
Cardiomegaly patent duct. arteriosus, r. ventr. & pulmonary artery hypertrophy	Cyst in internal meatus
Patent ductus arteriosus	Cochlear duct dilatation incip. cholesth. in tympanic membrane
Patent ductus arteriosus, fenestrated for. ovale, dilat. r. atrium, l. ventricle	Otitis media purul. ? neonat. (?1 days)
Patent ductus arteriosus, coarctation of aorta, ventral septal defect, patent for. ovale, hypoplasia of mitral valve ring	R.s. serous labyrinthitis, L.s. malformed stapes
Patent ductus arteriosus, coarctation of aorta, patent for. ovale, ventricular septal defect, endocardial sclerosis	Paget like islands in inner ear
Ventricular septal defect, hypertrophy r. ventricle	0
R. ventr. hypertr. & dilatation, l. ventr. hypertrophy focal endocard. hemorrhages	Paget-like islands in inner ear extravasates in endo- & perilymph spaces
Fenestration of cups of aortic valve, mural thrombus in cardiac ventricle	L.s. serous labyrinthitis
Interventricular septal defect, overriding aorta	0
Persistent ostium primum, persistent l. duct of Cuvier stenosis of aortic ring, cleft mitral valve, l. ventricular hypertrophy	Bilat. persistent stapedial artery
Dextrocardia, coarctation of aorta, septal defect	Hyalin mass in round window
Involvement of mitral valve, coronaries	R.s. otitis media (3 years)
Cyanotic heart disease	0
Marfan heart & pulmonary disease	Saccus endolymph. dilatation
Hurler coronary artery involvement	Chronic otitis media (4 years) b.s. ca. 60 db hearing loss, middle range
Fallot tetralogy	Malformed stapes & malleus
Fallot tetralogy (rubella)	L.s. chron. polypous otitis media
Maternal heart disease*	0
CNS	
Cerebral dysgenesis and atrophy microcephaly	Rosenthal canal empty
Microcephaly cong. defect of occipital lobe	Transudates, organizations
Microcephaly	Otitis med. supp.
Microcephaly 3 fontanelles, mongolism	0
Microcephaly overweight brain, tectorial hematoma inequity r. & l. post. fossa, anomalous circle of Willis	Low-set auricle, Paget-like islands in inner ear capsule
Microcephaly microgyria, hypoplasia of brain stem, shallow post. fossa, agenesis of olfactory bulb & optic nerves, microophthalmia, multifocal cerebral calcifications	Bilateral persistent stapedial artery
Microcephaly cebocephaly arhinencephaly Kundrat, cranial approximation of sutures	Hemorrhages int. meatus & subarcuate fossa
Absence of corpus callosum, hypoplasia of cerebellum, hypoplasia temporal & parietal bones	0
Microgyria	Ectasia tymp. scala, middle turn
Underweight brain, coronary synostoses	Saccus endolymph. dilatation
Occipital encephalocele	Otitis media & int. suppuration
Occipital encephalocele, hypoplasia of cerebellum, anomalous midbrain, shallow post. fossa, upward deviation of nerve roots	
Cerebral edema	Otitis media & int. cholest. sac. cyst in tympanic membrane
Cerebral edema, congestion, cephalhematoma	Organization, both windows, calcification in stria
	Otitis media neonat.
Calcification, cerebral cortex	Catarrhal otitis media
Degeneration anterior horn, spinal cord	Otitis media neonat.
Hypoplasia of olfactory organ, 5th nerve absence of septum pellucidum & corpus callosum, hypoplasia of cerebellum	Blood in vestibule & semicirc. canals
Cerebellar anomalies	Paget-like island in inner ear capsule
Central nervous system anomalies*	Hypoplasia, right ear
Anomalous growth of cerebellum	

	Aural pathology
"Involvement of brain	Anomalies of cochlear capsule, otitis media supp.
Platybasia, Dandy-Walker	0
Pierre-Robin	Low set ear, malformed pinnae
Spina bifida	Malformed cochlea
Erosion, ant. clinoid process, of petrous bone, malformation of cerebral fossae	Otitis media neonat.
Mongolism, rickets in father	Cochlear aqueduct dilatation, cyst in tympanic membrane
Mental retardation (13 years)	Cyst, inter. acoust. meatus
Poliomyelitis ant., interventricular & subarachnoid hemorrhages	0
Polioencephalitis	0
Maternal bulbar polio	0
Maternal acute polioencephalomyelitis	0
Congenital defect of occipital bones	Catarrhal otitis med., organizations
Signs of old meningitis	Otitis media neonat.
Lungs	
Hypoplasia of lungs	Incipient stapedial artery
Hypoplasia of lungs	Exostosis in int. ac. meatus exostosis in niche of round window
Hypoplasia of lungs, absence of lung fissure	Malformed stapes
Bilobed right lung	0
Atelectasis of lungs	Malformed stapes
Atelectasis of lungs	Ot. med. neonat.
Atelectasis of lungs, congestion, edema (Hurler)	R. otitis media
Pulmon. edema, congestion, hemothorax	Cyst, int. acoustic meatus
Hydrothorax, bilat.	Serous labyrinthitis
Pulmonary hyalin disease	0
Intestines	
Umbilical hernia	Hyalin mass in round window niche
Diaphragmatic hernia	0
Inguinal hernia	0
R. umbilical artery	0
Heterotaxy of viscera	Hypoplasia ext. ear
Heterotaxy of viscera	0
Situs inversus, hypoplasia of stomach	Exostosis inner meatus, exostosis niche of round window
Malrotation of intestines, annular pancreas, stenosis of duodenum	Malformed stapes
Intussusception, ileum	Scattered transudates in middle ea
Common mesentery for small & large intestines	Otitis purulenta neonat.
Celiac artery absence	Malformed stapes
Meckel diverticulum, non-attachment of mesentery, bands from duodenum to liver, to ileum, to cecum, diaphragmatic hernia	Paget-like islands in inner ear capsule
Meckel diverticulum, pancreatic ectopia, diastasis recti, partial failure of mesentery, hypoplasia iliac arteries	R. serous labyrinthitis, L. malformed stapes
Defect of diaphragm	0
Gastrointestinal hemorrhages	Many extravasates
Multiple gastric ulceration, gastric hemorrhage, absence of mesenteric attachments	0
Hemorrhages, subserous in ileum, colon	Malformed stapes
Pancreatic ectopia	Serous labyrinthitis, malformed stapes
Displacement of anus	0
Single umbilical artery	0
Single umbilical artery	0
Spleen	
Splenomegaly (hyperplasia of white pulp)	Otitis med.
Splenomegaly (hyperplasia of white pulp)	Cyst, inner acoust. meatus
Hepatosplenomegaly	Otitis media neonat.
Accessory spleen	Exostosis inner meatus, exostosis niche of round window
Accessory spleen	Hypoplasia r. external ear
Malformation of spleen"	0
Hypoplasia of all organs	0

	Aural pathology
Liver	
Hepatomegaly	0
Hepatomegaly	Chronic otitis med.
Hepatomegaly	Otitis med. neonat.
Hepatosplenomegaly	Catarrhal otitis, organizations
Congested liver	Paget like island inner ear capsule
Hepatitis, neonatal	Vestibule perilymph. edema, Reissner depressed
Necrosis liver & kidney	0
Hepatic cirrhosis (stillborn)	Exostosis inner meatus, exostosis niche of round window
Hepatic cirrhosis (13 years)	Cyst, inner acoust. meatus
Solitary cyst of liver	Otitis med. band formation
Kidney	
Absent l. kidney	0
Agenesis l. kidney	Dilated cochlear aqueduct
Bilat. agenesis of kidney & ureter	0
Immaturity of kidney	0
Immaturity of kidney	0
Renal hypoplasia	0
Renal hypoplasia	Ectasia tymp. scalae middle turn
Renal hypoplasia	Otitis med. neonatorum
Horseshoe kidney, multiple renal arteries	0
Nephromegaly	0
Nephromegaly, hemorrhage into calyces	Many inner ear hemorrhages
Renal ischemia	Cysts, inner acoust. meatus
Hydronephrosis	Otitis med. neonatorum
Hydronephrosis, hydroureter	Organizations, esp. in windows
Polycystic kidney	0
Polycystic kidney	Multiple hemorrhages, med. & int. ear
Polycystic kidney	Multiple exostoses
Polycystic kidney	Incipient stapedial artery
Calcification of renal cortex	Otitis media neonatorum
Nephritis	0
"Renal disease"	Catarrhal otitis med., organizations
Maternal nephritis	0
Adrenal cortex abnormalities	Organizations, both windows
Male sex organs	
Ureter agenesis	Origin of non-inflammatory cholesteatoma
Hydroureter	Organization in both windows
Pus in GI tract	0
Urachal cysts	Serous labyrinthitis, malformed stapes
Hypospadias	Cyst in int. acoustic meatus
Cryptorchismus	Malformed stapes
Undescended testicle	Transudates, organizations
Female sex organs	
Uterus duplex	Ectasia tympanic scala, medial turn
Uterus duplex	Bilat. stapedial artery
Uterus duplex	Incipient stapedial artery
Ovarian cyst	Paget-like islands in inner ear capsule
Prolapse of vaginal mucosa, with Gartner-duct remnant	0
Oligohydramnios	0
Intrauterine fetal death due to decidua placental degeneration	Intrauterine otitis
(Hysterotomy, bulbar polio)	
(Breech presentation)	Intrauterine otitis
(Face presentation)	Neonatus otitis, extravasates
Eye	
Micro-ophthalmia	Bilat. stapedial artery
Proptosis	Unilat. otitis media
Clouding of cornea	Malformed stapes & malleus
Coloboma palpebrae inf	Malformed stapes
Coloboma, bilat.	[illegible]
Hypoplasia of optic nerve	Otitis med. neonatorum

	Aural pathology
Skin	
Hirsutism	Otitis media
Scaly dry skin on chest	Very wide vestibular aqueducts, b.s.
Absence elastic tissue of skin	0
Petechiae, ecchymoses on epithelial surfaces	Endo- & perilymph extravasates in vestibule
Hemangioma of nose	Hyalin mass in round window
Pitting edema of extremities	Paget-like islands in capsular bone
Low hairline	Paget-like islands in capsular bone
Single imperforated central nostril	Hemorrhages, inner auditory meatus
Cystic hygroma of neck	Multiple hemorrhages [redacted] inner ear
Skeleton (outside skull)	
Skeletal changes, spinal column & skull	Otitis media
Fusion of ribs	0
Hemivertebrae, level of 5 & 7 cerv. vert.	0
Spina bifida	Cochlear malformation b.s.
Spina bifida occulta	Otitis purulenta neonatorum
Dislocation of cerv. vertebrae, micrognathia, bulk nose, narrow arched palate, dislocation of l. hip, l. talipes calcaneovarus	Paget-like island in inner ear capsule
Dislocation of hip	Neonat. otitis media & interna, serous & supp.
Small mandible, recession of chin, arched palate, Pierre-Robin	0
Micrognathia, glossoptosis	Stapedial deformity
High arched palate, short sternum, *fibrous defect in clavicle*, clenched fist, flexed great toes	Otitis media, stapedial deformity
Osteochondrodystrophy, dislocation of hips, high arched palate, arachnodactyly, arthrogryposis, wrist drop, Marfan syndrome	Dilated saccus r.s.
Hyperextensibility of joints	0
Cleft palate, choanal atresia, pectus excavatum	Absence of ext. meatus, agenesis of ossicles, stapedial deformity
Cleft palate, absence of thumbs, clubbing of hands, absence of radii	Absence of ext. meatus, malformed pinna
Club foot, club hand, 6 toes on each foot, bilat. talipes equinovarus	Bilat. stapedial artery
Club feet	Incipient stapedial artery
Club feet	Serous-hemorrhagic labyrinthitis
*Skeletal anomalies	Partial ectasia of tympanic scala in middle turn
*Multiple congenital anomalies	Hypoplasia, r. ear
Teeth dysodontia	Otitis med., Gaucher cells in cochlear capsule
Delayed dentition (11 months)	Saccus with edematous papillae

Table III

Syndromes	Aural pathology
Marfan (arachnodactyly)	Stenosis paret of vestibular aqueduct
Hurler (lipochondrodystrophy)	Organizations, ossifications, persistent mesenchyme
Tay Sachs (amaurotic familial idiocy)	Chronic mucopurulent otitis media
Hoffmann Werdnig (spinal progressive muscular dystrophy)	Slight inflamm. irritation, middle ear
Pierre-Robin (cleft palate, small mandible, glossoptosis)	0
Riley Day (familial dysautonomia)	Cong. hearing loss, dilatation of *vestibular aqueduct*
Autosomal trisomy	Mucopurulent otitis media, serous labyrinthitis
Fallot tetralogy (dextroposition of aorta, hypertrophy of r ventricle, ventricular septal defect, pulmonary stenosis)	Chronic otitis media (2½ years)
Dandy Walker (platybasia, cebocephaly)	Hemorrhages in inner meatus & subarcuate fossa
Trescher-Collins (dysostosis mandibulofacialis)	Malformed stapes
Mallory Weiss (bronchitis, upper GI bleeding)	*Dilatation of vestibular aqueduct b.s.*
Kundrat (k s lymphosarcoma)	Hemorrhage int. meatus & subarcuate fossa
Cuvier s duct (the common cardinal veins)	Bilat. persistent stapedial artery
Pendred (cong. deafness & goiter)	
Mongolism (trisomy 21)	Serous labyrinthitis, blood in cochlea

Table IV

Varia	Aural pathology
Congenital lues	Transudates, organizations
Leukemia, hemorrhagic diathesis	Many extravasates in endo- and perilymph spaces
Hemorrhages, many organs	Intrauterine otitis, serosanguinolent
Hypoproteinemia	Paget like islands
Cachexia, dehydration	0
Trisomy 17–18	*Malformed stapes*
Maternal diabetes mellitus	0
Thymic involution	Neonatus otitis
Hamartoma of thyroid	0
Hypertrophic lymph nodes, generalized	0 (3 years)
Ac. toxic reaction of lymphoid tissue	0

ODUCTION

acteristic features of the face, sometimes different from each other can be found g different human races. The nose an important part as this kind of acteristic feature of the face. The shape nose for each race and ethnic group ndamentally different and every mem of any race has a nose which is as nct and different from his neighbor's re his fingerprints.

d (1963) described different prototypes e profile of the face according to Greek, ptian, Renaissance, and modern sculp- s. As stated by Altman (1965) the pro- described by Baud mainly correspond he esthetic ideal of the particular era, to the racial characteristics. According him a prominent bony pyramid and tively small nasal bones are the main ferences between the noses of human ngs and the other primates.

e to the position and prominence of the e, it is subject to frequent injuries, which y cause a variety of deformities. Traumas y occur during fetal life, during delivery at any time after that. The factors of e, genes, and trauma are the three most portant factors which determine the ulti ate architecture of the nose.

cording to Williams (1956) all human ces have very similar functions but the se of a white man is especially efficient an air warming device while the nose of a negro is more effective as air-cooling apparatus than the white man's.

Very little attention has been paid to the relationship between a cosmesis and function. Only recently (Ogura *et al* 1964 Cottle, 1968 Ogura, 1970 Drettner 1970) has the significance of the functions of the nose to the functions of all other organs in the body become obvious. It has not, however been possible to find out what kind of a nose would be the most practical aid to the total organism considering racial differences, variations in climate, physical capacities required, and esthetic factors. As stated by Hinderer (1971) the interrelationship be tween nasal function and other functions of the body necessitates a thorough under standing of the complex structure of the nose and of its reaction to trauma, inflam mation and surgery

To solve the most complicated rhinologic problems concerning nasal structure and functions it seems apparent that modern computer analysis is necessary because the possible relationships to local and distant symptoms, racial, ethnic, and environmental factors, numerous notes from the clinical record like trauma, weight at birth, heredity state of health etc. have to be taken into consideration in correlation studies. It is also necessary to use rhinomanometric, ex aminations of nasal respiration to get figures, which can be handled by a computer

REVIEW OF LITERATURE

Anthropological Aspects of the Nose

General anthropological aspects

The shape of the nose has been one of the items of the anthropological studies which started towards the end of the eighteenth century (Slotkin, 1965). At the present state of the development of this science the length, height, and breadth of the nose and the relationships between these factors have been the objects of measuring. The nose of the white race is described as long and prominent while the negroid nose is broad and flat. In the case of the red and yellow races the measurements of the nose are somewhere between those two (Hinderer 1964). From the measurements of the nose different indices have been calculated for numerical description and anthropological characterization of the nose.

Characterization of the nose with indices and other nasal measurements

Schemes of some nasal indices are described in fig. 1. A detailed method of measuring these indices is presented later (pp 23—24). *The anthropological nasal index* described by Topinard (1878) can be measured only on the skull. Topinard also described *the cephalometric nasal index* which is measured on living subjects. It can further be subdivided into *a height-breadth index* and *a projection-breadth index*.

The height in living people is measured from nasale to subnasale. The nasale is a point on the skin over the nasofrontal suture in the midline. The subnasale is a point on the skin in the midline immediately below the anterior maxillary spine (anterior nasal spine). The breadth measures the degree of lateral expansion of the anterior nares on the level of nostrils. The antero-posterior projection is measured from the tip to the subnasale.

It has been stated by Williams (1956) that cephalometric nasal index is valuable on the basis of cosmesis so that it cannot be ignored in plastic surgery. Although there are many articles on anthropological nasal indices showing structural and racial differences, there is no indication (Hinderer 1964) that these indices could be applied clinically. *A clinical nasal index* was suggested in 1954 by Cottle (Hinderer 1964) in the evaluation and diagnosis of some rhinological problems.

$$\text{Anthropological nasal index} = \frac{100 \times \text{width of the nose}}{\text{height of the nose}}$$

$$\text{Height-breadth index} = \frac{100 \times \text{maximum breadth}}{\text{maximum height}}$$

$$\text{Projection-breadth index} = \frac{100 \times \text{maximum projection}}{\text{maximum breadth}}$$

Table 1 Division of index values in different race groups

Indices	Hyper leptorr	Leptorr	Mesorr	Chamaerr	Hyper chamaerr
Cephalometric nasal index	<55	55—69.9	70—84.9	85—99.9	≥100
Clinical nasal index		61>	61—65	65—80	
Tip index		60—75	75—80	≥80	
Salience index		55—65			

Cottle assumed that different anatomical types of noses had their own characteristic functional patterns. For instance, when reconstructive surgery of the nose is planned, the anatomical structure and functional pattern characteristic of the race to which the nose belongs must be taken into consideration (Williams, 1956).

A tip index whereby the tip or lobule can be measured has also been presented by Cottle (Hinderer 1964).

There is one *salience index* for each side of the nose. If the dorsum of the nose is prominent, the salience [redacted] high. In the white race the projection of the dorsum is 20 30 mm and the projection of the tip 34 42 mm (Cottle, 1960).

Index values in different race groups are seen in table 1. Hyperleptorrhine and leptorrhine = white race, mesorrhine = yellow race, chamaerrhine (platyrrhine) and hyperchamaerrhine = colored race (Williams, 1956, Hinderer 1964).

It is possible to get an even more precise total picture of the nose by using auxiliary examinations like measuring the sizes of separate structural elements and various angles (Joseph, 1967). An ideal nasolabial angle among white men is 85 90 among women slightly higher 95 105. In children it tends to be 100° or higher. The frontonasal angle should ideally be 30 38 (Schultz, 1918). Jennes (1954) has stressed the importance of photography in evaluating the appearance of external nose before and after operations.

Anthropology of the Finnish nose

The earliest ancestors of the present Finns immigrated to this country across the Gulf of Finland during the first thousand years A.D. (Nevanlinna, 1972). The population of the eastern parts of the country (Karelia) has probably also originated as a result of immigration from South Western Finland (Hornborg 1965). The present population of Kotka consists of natives of Kymenlaakso district as well as of Karelian evacuees. The population in Finland is quite young from a genetic point of view and in this respect the inhabitants of Kotka can indeed be considered as representing the population of the whole country. Despite the homogeneity of population foreign genetic interference from the east is possible but according to Nevanlinna this can only have happened to a small extent. This opinion has been based on certain examinations of blood groups.

Some studies of the characteristic features of the nose among the inhabitants of different provinces (historical provinces of Finland are presented in figure 2) have been made.

According to Retzius (1878) the inhabitants of Häme province have a small rather broad nose, which often has a small tip bent slightly upwards. The Karelians are said to have harmonious long noses. Karelian women have a straight and rather sharp nose.

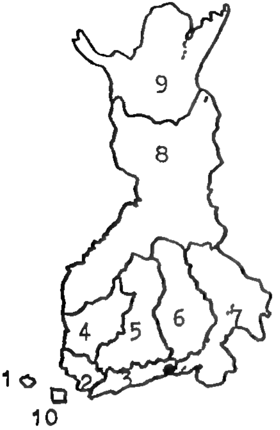
In the beginning of this century the methods of measuring the nose were slightly different from modern methods

In 1925 Arj Kajava gave directions as how to make anthropological examinations. He subdivided the nose into seven parts root, dorsum, tip alae, columella, nostrils and nares. The variations of the dorsum of the nose, for instance, were:

narrow ordinary broad, very concave, slightly concave, straight, slightly convex, very convex, irregular humpy long medium, short. The septum was not included in his examinations.

Figure 2 Historical provinces of Finland (1 9) and Turku archipelago (10)



The first systematic anthropological examinations of the inhabitants of our country were made by C v Haartman (1845) His references to the nose are, however rather few According to Haartman Karelians have a beautiful straight nose. The inhabitants of the province of Savo have a small nose and the inhabitants of Hame have a small snub nose. It seems to be a common opinion that Finnish nose has a concave profile. This belief is supported by the results of the examinations made by Mustakallio and Telkka (1951) as well as by Arho (1934) presented in table 2

In table 3 there are external nose indices and measurements. These results have been reached in examinations made in various provinces by Roschier (1931) Arho (1934) Pesonen (1935 1937) Lofgren (1937) Mustakallio and Telkka (1951) and Telkka (1953) The division of the noses into various types according to the same examinations is shown in table 4

In the beginning of this century the methods of measuring the nose were slightly different from modern methods.

In 1925 Y. I. Kajava gave directions as how to make anthropological examinations. He subdivided the nose into seven parts root, dorsum, tip alae, columella, nostrils and nares. The variations of the dorsum of the nose, for instance, were

narrow ordinary broad, very concave, slightly concave, straight, slightly convex, very convex, irregular humpy long, medium, short. The septum was not included in his examinations.

Functions of the Nose

Physiological aspects

The well known functions of the nose are the sense of smell and the warming moistening and cleansing of air before it enters th lungs The nose has defence and reflex functions and it also forms a resonance chamber in the formation of speech and sound A great number of local and distant symptoms caused by impaired nasal ventilation can easily be explained for instance by the fact that the normal nose secretes one liter of water per day moisturizing to approximately 90 % humidity the 10 000 liters of air passing through it (Holloway 1971)

According to Ogura (1970) pulmonary resistance increases and compliance decreases with advancing degrees of nasal obstruction These are observed during oral as well as nasal breathing Ogura also found that abnormal preoperative values reverted to normal range four to six months following successful nasal surgery in about 85 per cent of the cases tested. Measurements of resistance in the air passages during oral breathing appear to be reliable criteria for determining the need for nasal surgery (Ogura 1968)

According to Uddstromer (1940) there are no mouth breathers among healthy persons while 36 % of people with septal deviation were mouth breathers. Exercise that did not make any of healthy people mouth breathers caused oral breathing in 88 % of persons with septal deviation. According to Drettner (1970) a high percentage of persons with septal deviation have an absolute or relative nasal respiratory insufficiency

Nasopulmonary and nasobronchial reflexes have been assumed to give an increased bronchial tone in cases of nasal obstruction which would explain the reversibility of pulmonary changes after successful operation on the nose (Drettner 1970) According to Sercer (1930) blowing of air into one nostril causes an expansion of the corresponding side of the thorax. This reaction is absent when the nasal mucosa is anesthetized He showed (Sercer 1952) that mechanical chemical or thermal stimulation of the nasal mucosa induced a nasobronchial reflex which was principally homolateral Sercer also pointed out a disturbance in the acid-base balance of the blood in patients with nasal obstruction, and suggested that this might be due to reduced pulmonary ventilation.

Methods of estimation of nasal functions (screening tests)

Olfaction

According to Strauss (1970) olfactory acuity decreases considerably with age. In normal breathing only about two per cent of the molecules reach the olfactory epithelium (Wit, 1967) Hagan (1967) has stated that test substances should include some which produce weak odors and some which produce strong odors and that the odors should be familiar and thus easily identifiable. His list of easily available and useful substances includes the following progressing from weak odors to strong ones rosewater coffee cinnamon spirits of camphor lavender oil oil of cloves and peppermint extract. In addition some substance to test the trigeminal sensation is necessary and for this purpose household ammonia is recommended If the patient denies any sensation from ammonia one may be rather suspicious of psychological or malingering problems.

In 1923 Proetz described a simple accurate clinical method of quantitative olfactometry He used ten different chemicals each of them in ten different dilutions. The dilutions were 1/4 1/2 1 2 3 5 10 25 50 and 100 times the perceivable concentration The purpose was not to identify the substance but to get an olfactory sensation. Hansen (1966) used the same kind of series of concentrations His test substances were acetophenone, methyl salicylate, menthol and scatol

Ottoson (1956) demonstrated a slow negative potential in the olfactory area when this was stimulated with smell saturated air. The reaction was called electro-olfactogram. Stimulation with odorless air did not cause a corresponding reaction. According to some scientists (Osterhammel, Terkildsen and Zilstorff 1969) this system, however applied to human beings, is difficult and unpractical from the clinical point of view. Van Dishoeck (1965) used ethanol, benzene, and camphor as testing substances. The choice of solvent was significant. For instance in sesam oil ethanol gave an olfactory stimulus in concentration 1:100 but when glycerol was used as the solvent the ratio had to be 1:250. v. Dishoeck's study of 700 patients did not show any effect of smoking or pregnancy on olfactory acuity. Allergy however almost always caused hyposmia.

A previous head injury has a significant effect on the results of testing the acuity of smell. After cranial injuries Leigh, (1943) found anosmia in 7.2 % and Sumner (1964) in 7.5 % of the patients. Caruso, Hagan and Manning (1969) also found that the incidence and degree of hyposmia increased with the degree of head trauma.

R pi ii

An adequate airway alone is not enough to guarantee good nasal health. There must be in addition sufficient resistance to both inspired and expired air currents. According to Rohrer (1915) 47 per cent of the total resistance of air passages is created in the nose. In later examinations (Ferris *et al.* 1964) even higher percentages have been presented. The resistance in the nose is provided by free ends of the medial and lateral crura, the cul-de-sac, the upper lateral valve, and the floor of the pyriform aperture (Hinderer 1971).

Several different methods of examination have been developed that aim at objective measurement of nasal conductivity (Spoor 1965). This section mainly concentrates on the rhinomanometrical methods and the results of the nasal respiration obtained by them.

A criticism that has been raised to most rhinomanometric techniques is that the values of data obtained in models, cadaver noses and nasal casts, as to the quantity of air passing through the nasal chamber per unit time, the pressure differences between the airway opening and the pharynx and the velocities of the air are not comparable to those obtained in the living nose because of the obviously great differences in the conditions of the experiments (Williams, 1970).

According to Cottle *et al.* (1965) the pressure of normal single breath of inspiration is about 6–15 mm/H_2O while that of expiration is usually 2–4 mm/H_2O less. Insufficiency in the valve area or atrophy of the mucosa decreases the pressure whereas the stenoses and obstructions in the valve area or vestibulum increase it. In a normal nose the pressure after shrinkage is higher in the upper nostril and lower in lower nostril (subject lying supine, turning his head alternately to left and right) than in upright position, because the upper lateral cartilage comes closer to the septum in the upper nostril and vice versa in the lower nostril. If stiffness occurs in the valve area this change does not take place. If the mucosa is not shrunk, the lower turbinates become swollen increasing the pressure in the lower nostril.

According to Cottle *et al.* (1965) nasal breathing pressures are studied in three ways: 1) rhino-sphygmo-manometry, 2) rhino-revma-sphygmo-manometry, 3) flow-pressure relationship.

Rhino-sphygmo-manometry measures variations in nasal pressures while the air flows into the nose and out of it.

In rhino-revma-sphygmo-manometry the subject exhales or inhales through a flow

Functions of the Nose

Physiological aspects

The well known functions of the nose are the sense of smell and the warming moistening and cleansing of air before it enters th lungs *The nose has defence and reflex functions and it also forms a resonance* chamber in the *formation of speech and sound A great number of local and distant* symptoms caused by impaired nasal ventilation can easily be explained for instance *by the fact that the normal nose secretes* one liter of water per day moisturizing to approximately 90 % humidity the 10 000 *liters of air passing through it (Holloway 1971)*

According to some scientists (Orterhammel, Terkildsen, and Zilstorff 1969) this system, however applied *to human beings, is difficult* and unpractical from the clinical point of view Van Dishoeck (1965) used ethanol, benzine, and camphor as testing substances. The choice of solvent was significant. For instance in sesam oil ethanol gave an olfactory stimulus in concentration 1:100 but when glycerol was used as the solvent *the ratio* had to be 1 250. v Dishoeck's study of 700 patients did not show any effect of smoking or pregnancy on olfactory acuty Allergy however almost always caused hyposmia.

A previous head injury has a significant effect on the results of testing the acuity of smell. After cranial injuries Leigh, (1943) found anosmia in 7.2 ‰ and Sumner (1964) in 7.5 ‰ of the patients. Caruso, Hagan and Manning (1969) also found that the incidence and degree of hyposmia increased with the degree of head trauma.

R pl il

An adequate airway alone is not enough to guarantee good nasal health. There must be in addition sufficient resistance to both inspired and expired air currents. According to Rohrer (1915) 47 per cent of the total resistance of air passages is created in the nose. In later examinations (Ferris *et al* 1964) even higher percentages have been presented. The resistance in the nose is provided by free ends of the medial and lateral crura the cul-de-sac, the upper lateral valve, and the floor of the pyriform *aperture (Hinderer 1971)*

Several different methods of *examination* have been developed that aim at objective measurement of nasal conductivity (Spoor 1967). This section mainly concentrates on the rhinomanometrical methods and the results of the nasal respiration obtained by them.

A criticism that has been raised to most rhinomanometric techniques is that the values of data obtained in models, cadaver noses and nasal casts, as to the quantity of air passing *through the nasal chamber per* unit time, the pressure differences between the airway opening and the pharynx and the velocities of the air are not comparable to those obtained in the living nose because of the obviously great differences in the conditions of the experiments (Williams, 1970)

According to Cottle *et al* (1965) the pressure of normal single breath of inspiration is about 6 15 mm/H_2O while that of expiration is usually 2 4 mm/H_2O less. Insufficiency in the valve area or atrophy of *the mucosa decreases the pressure whereas the* stenoses and obstructions in the valve area or vestibulum increase it. In a normal nose the pressure after shrinkage is higher in the upper nostril and *lower* in lower nostril (subject lying supine, turning his head alternately to left and right) than in upright position, because the upper lateral cartilage comes closer to the septum in the upper nostril and *vice versa in the lower* nostril. If stiffness occurs in the valve area this change *does* not take place. If the mucosa is not shrunk, the lower turbinates become swollen increasing the pressure in the lower nostril.

According to Cottle *et al* (1965) nasal breathing pressures are studied in three ways 1) rhino-sphygmo-manometry 2) rhino-revma-sphygmo-manometry 3) *flow* pressure relationship

Rhino-sphygmo-*manometry measures* variations in nasal pressures while the air flows into the nose and out of it.

In rhino-revma sphygmo-manometry the subject exhales *or inhales* through a flow

meter certain volumes of air per minute visually controlled.

In determining nasal flow pressure relationship flow and pressure can be recorded synchronously on a two channel recorder. The pressure is usually measured with a manometer connected to a tube coming from a nostril (anterior rhinomanometry). Measuring can also be done with the subject having a catheter in his mouth (v. Dishoeck 1964) (posterior rhinomanometry). In this way the total pressure of both nostrils can be measured. Unfortunately this kind of posterior recording is only possible in about 50 % of patients due to the sensitive swallowing reflex (Kortekangas 1971).

The evaluation and diagnostic value of rhinomanometric results is based on empirical experiments with a great number of patients. Cottle (1968) reported a connection between certain aberrations of pressure curves and certain pathological states of noses. 1) Irregularities of breathing pattern amplitudes or frequency are often noted and usually denote local derangements within the nose. 2) A marked increase in breathing pressure practically always means a nasal obstruction and is especially predominant if the stenosis is in the area of a nasal valve. 3) If the pressure level at the height of expiration persists for 2 to 4 seconds this "flat top" aberration nearly always indicates the presence of the impaction of the septal spur or ridge in the posterior portion of the nose. 4) Low inspiration and expiration pressures ranging from 3 to 5 mm/H_2O or less are frequently found a) nasal chambers are abnormally wide b) patients are obese or asthenic c) there are localized mucosal involvements or an extreme sensitivity of the nasal mucosa. 5) After each completed breathing cycle there is a pause of 2—8 seconds during which there is no positive or negative pressure. Cottle has referred to this as a "mid cycle rest". According to him it is never a normal finding and is often seen in patients who have had difficult nasal breathing for several years. In Cottle's experience this aberration is often a sign of recent or old heart disease. Rapidity of breathing is often observed in children with adenoid obstruction or in adults with pulmonary disease. Uneven and unequal breathing patterns are often seen in emotionally disturbed people. The rate of normal breathing ranges from 10 to 18 times a minute.

Relations between Nasal Structure, Function, and Symptoms

A structural disproportion in the nose creates a variety of clinical symptoms which Cottle (1965) has described as the syndromes of nasal disharmony. For example, the white person having the disproportions of a high nasal index and low wide flattened nose, resembling that of negro type, will often manifest functional disturbances in breathing due to alteration of the direction and velocity of the air currents.

Disproportions of nasal structure may produce a great variety of symptoms and complaints referable to the nose such as referred pain, considerable postnasal discharge, recurrent sore throat, cough etc. (Williams 1956). Nasal malformations often result from injuries to the external pyramid that may stop the growth or accelerate it in the injured area. Thus the nose of a grownup person may be a most complicated combination of parts at different levels of development.

According to Hinderer (1964) the following symptoms occur most frequently in the abnormally wide nose: crusting and occasional bleeding, stuffiness of the nose, changes in ability to smell and taste, indefinite facial pains, headache, postnasal discharge, chronic sore throat, persistent cough, recurrent stuffy ears, and chronic fatigue.

Ballooning of upper laterals decreases the sensation of the resistance to the inspired air and causes sensation of nasal blockage as

in atrophic rhinitis where again the airway is increased. Stretching of upper laterals by an excessively high septum produces a narrowing of the angle between the septum and the upper lateral and predisposes to a collapse of the cartilage on inspiration and produces a sensation of nasal obstruction. It has been called a »tension nose» and is accompanied by symptoms of nasal malfunction (Hinderer 1971). Returning of the upper lateral cartilages produces stiffening of the cartilage, stretching of the mucous membrane and impaired valve function (Cottle, 1960).

Even slight septal deviation can be of considerable importance if it is situated in the valve area. Septal spur or ridge in the most posterior part of the nose is near the region of the sphenopalatine ganglion causing many local and distant symptoms because of the irritation of the ganglion. Cottle (1960) has stated that the impaction is the state in which the nasal septum makes constant contact with the lateral wall of the nasal chamber despite shrinking of the mucosa by medication. If contact is broken by medication, the septal deviation is considered an obstruction.

A sleeping person changes his position many times each night. As stated by Masing and Horbaschk (1969) these movements are mainly directed by the nose. In a lateral sleeping position a person is breathing more through the upper side of nasal cavity. If the upper nostril is obstructed, the congestion of the turbinates in the lower nostril makes breathing through the nose impossible and forces a person to sleep with the obstructed nostril downwards or breath through the mouth.

According to Ogura (1968) there was a definite tendency toward decreased one second vital capacity and maximum ventilatory volume of the lungs in abnormally obstructed noses. He used anatomical and physiological classification of nasal obstruction some features of which are presented below

— normal nose
0 straight septum, free airway
1 straight septum, slight enlargement of conchae
2 deviated septum with minimal intermittent nasal obstruction

— abnormal nose
3 deviated septum, fixed unilateral obstruction
4 anterior deviation of septum, impaction unilateral, upper lateral cartilage collapse unilateral, moderate obstruction
5 bilateral upper lateral cartilage collapse, moderate bilateral nasal obstruction
6 severe bilateral septal deviation, severe permanent bilateral nasal obstruction

Cinelli (1971) claims that it is also possible to draw conclusions about the traits of human personality from the shape of the nose.

Environmental Effects on Nasal Functions and Symptoms

Smoking habits

There are only a few remarks about the effect of smoking on nasal symptoms or functions in the literature (v Dishoeck, 1965 Hinderer 1971). On the other hand there are several remarks in the literature about the popularity of smoking. Physicians are a special group among smokers, because they are probably more aware of the dangers of smoking than other people. According to an examination made in Finland in 1969 (Vuori *et al.* 1972) only 28 per cent of the physicians in Finland were regular smokers (17 % of women and 24 % of men). Ten per cent smoked sometimes and 44 % had never smoked. In the 30–39 age group 26 per cent were regular smokers and in the 40–49 age group 25 per cent.

Hirvonen (1969) has collected from various examinations some percentages concerning the incidence of smoking in the 1960's of the schoolgirls in the fifth forms of the secondary schools in Helsinki 29.2 % were smokers, while of boys in the same forms 41.8 % smoked. 19 % of female and 47 %

meter certain volumes of air per minute visually controlled

In determining nasal flow pressure relationship flow and pressure can be recorded synchronously on a two channel recorder

The pressure is usually measured with a manometer connected to a tube coming from a nostril (anterior rhinomanometry) Measuring can also be done with the subject having a catheter in his mouth (v Dishoeck 1964) (posterior rhinomanometry) In this way the total pressure of both nostrils can be measured Unfortunately this kind of posterior recording is only possible in about 50 % of patients due to the sensitive swallowing reflex (Kortekangas 1971)

The evaluation and diagnostic value of rhinomanometric results is based on empirical experiments with a great number of patients Cottle (1968) reported a connection between certain aberrations of pressure curves and certain pathological states of noses 1) Irregularities of breathing pattern amplitudes or frequency are often noted and usually denote local derangements within the nose. 2) A marked increase in breathing pressure practically always means a nasal obstruction and is especially predominant if the stenosis is in the area of a nasal valve. 3) If the pressure level at the height of expiration persists for 2 to 4 seconds this «flat top» aberration nearly always indicates the presence of the impaction of the septal spur or ridge in the posterior portion of the nose. 4) Low inspiration and expiration pressures ranging from 3 to 5 mm/H_2O or less are frequently found a) nasal chambers are abnormally wide b) patients are obese or asthenic, c) there are localized mucosal involvements or an extreme sensitivity of the nasal mucosa 5) After each completed breathing cycle there is a pause of 2—3 seconds during which there is no positive or negative pressure. Cottle has referred to this as «a mid-cycle rest» According to him it is never a normal finding and is often seen in patients who have had difficult nasal breathing for several years. In Cottle's experience this aberration is often a sign of recent or old heart disease. Rapidity of breathing is often observed in children with adenoid obstruction or in adults with pulmonary disease. Uneven and unequal breathing patterns are often seen in emotionally disturbed people. The rate of normal breathing ranges from 10 to 18 times a minute.

Relations between Nasal Structure, Function, and Symptoms

A structural disproportion in the nose creates a variety of clinical symptoms which Cottle (1968) has described as the syndromes of nasal disharmony For example, the white person having the disproportions of a high nasal index and low wide flattened nose, resembling that of negro type, will often manifest functional disturbances in breathing due to alteration of the direction and velocity of the air currents

Disproportions of nasal structure may produce a great variety of symptoms and complaints referable to the nose such as referred pain considerable postnasal discharge recurrent sore throat, cough etc. (Williams 1956) Nasal malformations often result from injuries to the external pyramid that may stop the growth or accelerate it in the injured area. Thus the nose of a grownup person may be a most complicated combination of parts at different levels of development

According to Hinderer (1964) the following symptoms occur most frequently in the abnormally wide nose crusting and occasional bleeding stuffiness of the nose changes in ability to smell and taste, indefinite facial pains headache, postnasal discharge, chronic sore throat, persistent cough recurrent stuffy ears and chronic fatigue.

Ballooning of upper laterals decreases the sensation of the resistance to the inspired air and causes sensation of nasal blockage as

It has been found (Jeppesen and Winfeld, 1972) that the infants of primiparae, obviously due to a prolonged delivery had considerably more septal dislocations than those of multiparae. According to them, in a series of 907 newborn infants, who were all examined rhinologically the frequency of septal dislocations was 3 19 %. The frequency was not significantly higher in heavy newborn infants.

According to Hinderer (1971) among normally delivered white babies at least 5 per cent have marked deformities of the nose and 30 50 per cent have temporary flattening He has also stated that injuries during periods of rapid growth, i.e. 1 5 years and 10 15 years, cause greater disturbances.

of male students were smokers In the armed forces 64 6 % of the privates and 52.5 % of the officer cadets smoked. Of dock work ers in the 25 49 age group 54 1 % were smokers.

Working conditions

Some studies have been made on the amount of subjective disadvantages in working con ditions (Saari 1972) and about the effect of disadvantages on nasal symptoms or functions (Meurman 1948 Kereković 1971) For instance, of 3 886 people the following percentages said that they suffered from *certain disadvantages (Table 5)*

Table 5 Subjective disadvantages in working conditions according to Saari (per cent)

Disadvantage in working condition	continuous disturbing	temporary disturbing	not disturbing
High humidity	3	6	91
Temperature variations	15	26	59
Impurities in air (dust)	10	19	71
Chemicals (gaseous)	10	15	75
Draught	19	23	58

According to an examination (Lehto 1972) made by Tyoterveyslaitos (Institute of Oc cupational Health) in 1970 46 per cent of workers said that they suffered from a too high or too low temperature, 23 per cent suffered from humidity 20 per cent from impurities of air 22 per cent from chemi cals and 65 per cent from draught.

Meurman (1948) *has* investigated the inci dence of nasal symptoms in specific parts of the lime and cement factories in Finland Working conditions in these factories were very dusty Epistaxis was the complaint of 0.5 per cent of the mine and crusher house workers, 8 6 per cent of the cement workers and 39.5 per cent of the lime workers. The *chronic symptoms* were present in average as follows rhinitis 27 per cent, throat trouble 8 per cent cough 15 per cent, and impaired sense of smell 11 per cent. Accord ing to the slightly modified Proetz tech nique the sense of smell was *impaired in* 44 4 per cent of 394 subjects tested

Growth of the Nose

Schultz (1920) found that the clinical nasal index was *different between* whites and negroes even in fetal life, decreasing in both races after birth At the age of five or six in the normal white child the nostrils have a tendency to narrow and increase in anteroposterior projection with a decrease in the clinical nasal index. In the colored child the nose becomes wider and more flattened and the *nostrils* become oval with an in crease in the clinical nasal index.

Variations in the structure and function of the *nose* are usually caused by disturbance during the development of the nose or an injury that has happened later According to what Becker (1964) says in the textbook of human genetics, genetically based mal formations of the nose are fairly rare.

According to Hillenbrandt (1933) disturb-ances in the growth can rather often be *found in the cartilaginous septum of fetus* This may be the reason for the later mal formations. Leicher and Bergman (1958) have examined the inheritance of nasal de *formities. If both the parents* had a devia tion of the septum it was also found in 80 % of their children If only one of the parents had the deviation it could be found in *55* per cent *of the children and* if the septums of both parents were straight, only 10 % of the children had a deviation Ac cording to Tepan (1970) the deviation of the septum may be inherited but the dislo cation of the septum *cannot* be *inherited* He had examined 30 cases of dislocation of the septum. In 17 cases it was caused by an injury and in six cases by a difficult prolonged delivery

It has been found (Jeppesen and Winfeld, 1979) that the infants of primiparae, obviously due to a prolonged delivery had considerably more septal dislocations than those of multiparae. According to them in a series of 907 newborn infants, who were all examined rhinologically the frequency of septal dislocations was 3.19 %. The frequency was not significantly higher in heavy newborn infants.

According to Hinderer (1971) among normally delivered white babies at least 5 7 per cent have marked deformities of the nose and 30 50 per cent have temporary flattening He has also stated that injuries during periods of rapid growth, i.e. 1 5 years and 10 15 years, cause greater disturbances.

of male students were smokers In the armed forces 64 6 % of the privates and 52.5 % of the officer cadets smoked Of dock workers in the 25 49 age group 54 1 % were smokers.

According to Tepan (1970) the deviation of the septum may be inherited but the dislocation of the septum cannot be inherited He had examined 30 cases of dislocation of the septum In 17 cases it was caused by an injury and in six cases by a difficult prolonged delivery

URPOSE OF THE STUDY

he relation of nasal symptoms to structural isturbances has been recently empha ized by rhinologic surgeons. This study was lanned to estimate the incidence of nasal tructural disturbances among adults se ected by an equal interval sampling By sing some simple tests in addition to inter views about relevant matters, correlations of nasal symptoms and signs were studied. In the light of the facts revealed this study attempts to answer the following questions

1 Is the way of selecting test subjects for this study acceptable?

2 What is the incidence of nasal disorders among unselected adult population?

3 Are there any special racial features of the nose in this material?

4 How reliable are the methods of testing used in this study?

5 What are the norms for the rhinomanometric values obtained in this study?

6 Which is the incidence of significant correlations between nasal symptoms and signs in relation to general health and environmental circumstances?

PURPOSE OF THE STUDY

The relation of nasal symptoms to structural disturbances has been recently emphasized by rhinologic surgeons. This study was planned to estimate the incidence of nasal structural disturbances among adults selected by an equal interval sampling. By using some simple tests in addition to interviews about relevant matters, correlations of nasal symptoms and signs were studied. In the light of the facts revealed this study attempts to answer the following questions

1 Is the way of selecting test subjects for this study acceptable?

2 What is the incidence of nasal disorders among unselected adult population?

3 Are there any special racial features of the nose in this material?

4 How reliable are the methods of testing used in this study?

5 What are the norms for the rhinomanometric values obtained in this study?

6 Which is the incidence of significant correlations between nasal symptoms and signs in relation to general health and environmental circumstances?

MATERIAL AND METHODS OF THE STUDY

Selection of Subjects for the Study

Two hundred people in anthropological age (from 25 to 50 years) were randomly selected for this examination by equal interval sampling from the offical register of the town of Kotka (33 000 inhabitants). They were invited by letter and informed about the examination of the nose and upper respiratory system. The test was said to take one hour and to be free. The reasons for those 38 who did not attend were, two were not willing nine peole did not come because their work did not permit it, because they were ill or because their addresses were unknown and one was dead. In twenty-six cases the reason for absence remained obscure.

Table 6 Availability of subjects chosen by sampling

	women	men	total
Examined	91	71	162
Absent	18	20	38
	109	91	200

Methods Applied in Examination of Each Subject

Clinical examination and filling in the questionnaire

The questionnaires were filled in by the author who also took the photographs and carried out the measurements and tests. Both the symptoms and signs related to the subjects of this investigation were transferred to a certain form suitable for computer analysis. Every investigation started with an inquiry including 61 questions, about background variables (page 25) The subjects were asked for their opinions and encouraged to be spontaneous. The classification of the answers into 3—7 statistical groups according to the frequency or severity of symptoms was decided by the author The clinical description consisted of 6 olfactory and 30 rhinomanometrical measurements, 8 indices were measured and checked by photography In addition 48 evaluations were made of the structure and / or state of pyramid, septum, turbinates, skin, mucous membrane, nasopharynx, secretion of the nose, and phonation.

Measuring the indices

The clinical nasal index and the tip index were selected because of their supposed clinical importance (Hinderer 1964) as a means of evaluating the structure of the nose in this study (Fig 1). The salience index was also included.

$$\text{Clinical nasal index} = \frac{100 \times \text{maximum width between pyriform crests}}{\text{height of the nose}}$$

$$\text{Tip index} = \frac{100 \times \text{width at level of apex of nostrils}}{\text{width at widest expansion of alae}}$$

$$\text{Salience index} = \frac{100 \times \text{greatest projection of the dorsum}}{\text{projection of the tip}}$$

measurements. On the basis of these results the minute volume was determined at rest, after exercise, and during maximal nasal ventilation. During the examination the subject's nose was under an airtight diver's mask. Master Step was used as a form of exercise. During the period of thirty seconds the subject stepped 15 times on to a bench that was 40 cm high. The measurement was taken one minute after the beginning of the exercise. Finally the maximal nasal ventilation was examined and here again the diver's mask was used. The subject was asked to breathe maximally through both nostrils. The subject was in a sitting position during the test.

To determine the norms for the rhinomanometric readings, the limiting values of the middlemost 50, 60 and 80 per cent were determined from inspiration and expiration pressures as well as from the volume of maximal nasal breathing for both sexes separately.

Vitalogram

The vital capacity of the lungs (VC), the maximal ventilatory volume (MVV) and the volume of forced expiration at 0.5 seconds (FEV $_{.5}$) were determined by vitalogram (Vitalograph[R]). These values can be read according to the age and height of the subject from the nomogram (Kory et al 1961). Maximal ventilatory volume is obtained from the equation FEV $_{.5}$ x 40 (Kennedy 1953, Cara, 1953). The vitalogram test was made three times by every subject, and the best reading was accepted.

Tension test

The degree of the tension of the nose was examined by using a tension test. The subjects were asked to say oo [u], at the same time the degree of coming down of the tip was observed. If there was no movement of the tip, the result was negative.

Statistical Methods

The effects of background or environmental factors (i.e. background or independent variables) on the nasal symptoms and results of functional tests (i.e. dependent variables) were analyzed statistically.

Independent variables

The following items were used as background variables: sex, age, height, working conditions, previous operations, heredity, incapacitating diseases, previous diseases, recent medicines, smoking habits, sleeping position, nasal indices, skin and mucous membranes, appearance of external nose, nasal septum, vestibulum, and valve area.

Dependent variables

Nasal symptoms (= nasal symptom complex) and results of olfactory, trigeminal, rhinomanometric, and tension tests (= nasal sign complex) were used as dependent variables. A vitalogram examination was used for the comparison of nasal and pulmonary functions.

Nasal symptom complex

Eleven of the nasal symptoms of this study were applied to characterize unsatisfactory function of the nose (table 25). According to the intercorrelations of these symptoms a nasal symptom complex was formed on the basis of the following five items: dryness of throat, sneezing, postnasal discharge, snoring, and mouth breathing (table 26). Every item ranged from 1 to 3 points (for instance: continuous = 1, frequent = 2, seldom or never = 3). The total number of points (5—15) changes with the presence or absence of symptoms and can be used as a variable in correlation studies.

Olfactory complex

An olfactory complex of four items (olfactory stimuli I and II, right and left nostril

The width of the nose is determined by feeling the lateral edges of the pyriform crest through the skin and measuring the distance between them The height is measured *from nasale to subnasale.*

The measurements in tip index are the width of the base of the nose on the level of apex of each nostril and the widest expansion of the alae. The projection of the bony dorsum is measured from the baseline to the greatest prominence of the dorsum with the ruler *held perpendicular to the dorsum* The projection of the tip is measured from the alar facial groove to the tip of the nose (Cottle 1960)

Photography

Four slides a frontal view two lateral views and a base view were taken of every subject against a dark green background. A scale was enclosed in the photographs to make it possible to enlarge the slides to the standard size. In frontal view the same amount of each ear was visible and the Frankfort Horizontal line (Hinderer 1971) from the tragus to the suborbital was parallel to the floor In lateral views also the *Frankfort line was horizontal and only one* eyebrow was visible In base view the head was bent back until the tip of the nose reached the line between the eyebrows The slides were projected on the screen for measuring indices

Olfactory and trigeminal tests

The aim was to determine roughly the acuity of the sense of smell of the subjects. For that purpose two different olfactory stimuli (coffee = O_1 and cocoa = O_2) and one trigeminal stimulus (vinegar = T) were used Each nostril was tested separately The mucous membrane had not been shrunk at the beginning of the examination. The narrower nostril was always tested first If there was any difference between the nostrils in acuity while testing by the first stimulus the following tests were first made to the less efficient nostril The test substances were renewed weekly to keep them fresh and they were familiar to everbody

Rhinomanometry

Equipment

The rhinomanometric apparatus consisted of pneumotachograph model Fleich AM 282 Elema transducers EMT 32 and EMT 33 Elema amplifier EMT 31 Elema writer *Mingograph 34 with an inbuilt volume in*tegrator and a micromanometer for calibration.

Pressure tests

First an anterior rhinomanometry was performed while the subject was supine. Inspi*ratory and expiratory pressures were re*corded separately from the right and left nostril The opposite nostril was closed air tightly with a nozzle which did not distort the septum or the nostril under examination The same *examination was renewed after* the mucous membrane had been shrunk After that the breathing pressures were examined turning the head of the subject alternately with right and left side of the nose up and the *decrease in the breathing* pressure caused by dilatation of the upper nostril was measured at the same time The averages of 4—5 successive deviations above or below the baseline of the rhinogram were determined to represent *respectively* expiration or inspiration of the subject.

Flow tests

Flow tests were performed separately after pressure tests The frequency of nasal breathing and the volume of a single breath were measured from a volume curve Also here 4—5 successive deviations were used as a basis for measurements The lower edge of the line was *always used as the point of*

measurements. On the basis of these results the minute volume was determined at rest, after exercise, and during maximal nasal ventilation. During the examination the subject's nose was under an airtight diver's mask. Master Step was used as a form of exercise. During the period of thirty seconds the subject stepped 15 times on to a bench that was 40 cm high. The measurement was taken one minute after the beginning of the exercise. Finally the maximal nasal ventilation was examined and here again the diver's mask was used. The subject was asked to breathe maximally through both nostrils. The subject was in a sitting position during the test.

To determine the norms for the rhinomanometric readings, the limiting values of the middlemost 50, 60 and 80 per cent were determined from inspiration and expiration pressures as well as from the volume of maximal nasal breathing for both sexes separately.

Vitalogram

The vital capacity of the lungs (VC), the maximal ventilatory volume (MVV) and the volume of forced expiration at 0.75 seconds (FEV .75) were determined by vitalogram (Vitalograph ®). These values can be read according to the age and height of the subject from the nomogram (*Kory et al.* 1961). Maximal ventilatory volume is obtained from the equation FEV .75 x 40 (Kennedy 1953, Cara 1953). The vitalogram test was made three times by every subject, and the best reading was accepted.

Tension test

The degree of the tension of the nose was examined by using a tension test. The subjects were asked to say oo [u], at the same time the degree of coming down of the tip was observed. If there was no movement of the tip, the result was negative.

Statistical Methods

The effects of background or environmental factors (i.e. background or independent variables) on the nasal symptoms and results of functional tests (i.e. dependent variables) were analyzed statistically.

Independent variables

The following items were used as background variables: sex, age, height, working conditions, previous operations, heredity, incapacitating diseases, previous diseases, recent medicines, smoking habits, sleeping position, nasal indices, skin and mucous membranes, appearance of external nose, nasal septum, vestibulum, and valve area.

Dependent variables

Nasal symptoms (= nasal symptom complex) and results of olfactory, trigeminal, rhinomanometric, and tension tests (= nasal sign complex) were used as dependent variables. A vitalogram examination was used for the comparison of nasal and pulmonary functions.

Nasal symptom complex

Eleven of the nasal symptoms of this study were applied to characterize unsatisfactory function of the nose (table 25). According to the intercorrelations of these symptoms a nasal symptom complex was formed on the basis of the following five items: dryness of throat, sneezing, postnasal discharge, snoring, and mouth breathing (table 26). Every item ranged from 1 to 3 points (for instance: continuous = 1, frequent = 2, seldom or never = 3). The total number of points (5—15) changes with the presence or absence of symptoms and can be used as a variable in correlation studies.

Olfactory complex

An olfactory complex of four items (olfactory stimuli I and II, right and left nostril

tested separately) was used for a combined olfactory variable Every item ranged from 1 to 3 points (no sensation = 1 positive sensation = 2 stimulus identified = 3) Here again the total number of points (4—12) obtained by the subject was used as a basis for correlation studies

Trigeminal complex

A trigeminal complex of two items (stimulus in right and left nostril) was used for a combined trigeminal variable ranging from 1 to 3 points according to the same system as olfactory items (no sensation = 1 positive pungent sensation = 2 identified = 3) From 2 to 6 points could be obtained by one person.

Pressure complex

To make the results of nasal pressure changes applicable for correlation studies the averages of pressures in all groups (no medication, after shrinkage inspiration expiration right nostril and left nostril) were evaluated also taking age into consideration In every group the pressures of the subject were compared to the mean value and according to the percentage deviation from it the results ranged from 1 to 3 points Low quartile = 1 middlemost 50 per cent = 2 and high quartile = 3 points.

Flow complex

The mean volumes of maximal nasal ventilation were grouped according to the age and height of the subjects Percentage deviatons of the volume readings from the averages were divided into quartiles, which were used as in the case of the pressure complex.

Correlation studies

To examine the correlations of nasal symptoms and signs frames of reference were formed using the background variables and dependent variables of this study as a basis Significant positive or negative correlations were expressed respectively with signs + or — and the degree of significance was expressed by * as an exponent of the sign Non significant correlation was expressed by the sign ▫ The following levels of significance were chosen.

$$0.05 \geq p > 0.01$$
$$0.01 \geq p > 0.001$$
$$0.001 \geq p$$

significant level for 162 cases is	r =	.154
91	r =	.205
71	r =	.232
162	r =	.202
91	r =	.267
71	r =	.302
162	r =	.256
91	r =	.339
71	r =	.330

RESULTS

Background Variables

Sex age and height

The 162 subjects of this study were investigated in relation to all variables. There were 91 women and 1 men among the subjects.

The distribution of the age of the subjects is given in table 7 The ages are divided into three approximately equal groups to permit correlation anlysis. The distribution into four height groups is given in table 8, and the mean height values in different age groups are presented in table 9 The tendency of increasing height among younger people could be seen.

Table 7 Distribution of subjects into age groups and mean ages (years)

Age years		per cent	Mean age (years)	
25	34	36 6	Male	37 9 years
35	40	28 0	Female	37 1
41	50	35 4	Total	37 4

Table 8 Distribution of subjects into height groups and mean heights (cm)

Height cm		per cent	Mean height (cm)	
	160	20 5	Male	174 9 cm
161	170	42 9	Female	162 1 cm
171	180	30 4	Total	167 7 cm
181		[illegible]		

Table 9 Mean height of the subjects in different age groups

Age years		Mean height cm	
		Male	Female
25	34	176 8	163 2
35	40	175 8	16[illegible] 0
41	50	[illegible] 5 6	161 1

Working conditions

The opinions of the test subjects about their working conditions are analysed in table 10. For retired subjects (five) and housewives (17) the living surroundings were taken to represent their working conditions. 16 per cent were mainly outdoor workers [illegible] per cent were mainly indoor workers, and 15 per cent had about equal amounts of out door and indoor work.

Table 10 Subjective opinion of the subjects about their working conditions (per cent)

Working condition	Continuously disturbing	Temporarily disturbing	Not disturbing
High humidity	4	9	87
Temperature variations	7	30	63
Impurities in air (dust)	15	25	60
Chemicals (gaseous)	6	12	82
Draught	9	36	55

In table 11 the incidence of outdoor or in door work is correlated to the amount of subjective disadvantages in working conditions.

Table 11 Correlation of working conditions to the subjective disadvantages[1])

Disadvantage in working conditions	Outdoor/indoor work
High humidity	O
Temperature variations	+
Impurities in air (dust)	+
Chemicals (gaseous)	+

Recent medicines

Long term usage of medicines can be assumed to have some effect on the functions of the organism. The usage of medicines (during five recent years) examined in this study has however in many cases been temporary so that the results are not the same as they were during treatment with antibiotics, antihistamines cortisone or nose drops. Oral contraceptives which are very commonly used among women, and antihypertensives are, however used during long periods and regularly (table 14).

Table 14 Recent usage of medicines among the test subjects (per cent)

Medicine	Frequent	Seldom	Never
Antibiotics	9	67	24
Antihistamines	3	3	94
Cortisone	1	4	95
Nose drops	1	34	65
Oral contraceptives (women)	25	22	53
Antihypertensives	2	2	96

Smoking habits

47.5 per cent of all the subjects were smokers. 70.4 per cent of the men and 29 per cent of the women smoked. The readings are relatively high compared to the results obtained by Vuori *et al* (1972) and Hirvonen (1969). Because about one half of the subjects were non-smokers, the effect of smoking on the symptoms and signs of the nose will be examined carefully in this study. A more detailed analysis of smoking habits can be seen in tables 15 and 16.

< 5 years	3
non-smoker	53

Outdoor work was experienced significantly disadvantageous as far as temperature variations and the presence of impurities and chemicals in inspired air were concerned High humidity and draught on the other hand were equally disturbing in both indoor and outdoor work.

Previous operations

Although the subjects were randomly selected none of them had had a previous septum or pyramid operation One had had a maxillary sinus operation polypi had been removed from two persons, and four of them had had a turbinate operation. Adenoidectomy had been made in 4 9 per cent and tonsillectomy in 15 4 per cent

Heredity

The subjects were asked about the incidence of asthma allergic rhinitis chronic infectious rhinitis, and heart diseases among close relatives (grandparents, parents brothers and sisters and children) (table 12) The subjects seemed to have a very clear idea about the heart diseases of their relatives but the notes about nose troubles among the relatives were more or less guesses Apparently only the incidence of heart diseases and asthma can be used reliably while examining intercorrelations of heredity and nasal symptoms and signs

Table 12 The incidence of nasal respiratory and heart diseases among close relatives (per cent)

Symptoms	Frequent	Occasional	None
Rhinitis chr	[illegible]	5	[illegible]
Rhinitis allerg	1	8	91
Asthma	3		75
Heart disease	1	30	55

Incapacitating diseases

Eleven of the subjects were suffering from a serious disease that obviously lowered their functional capacity The diagnoses were 1 multiple sclerosis 1 pulmonary emphysema 1 hypertension 1 pulmonary silicosis, 1 hypothyroidism 1 pulmonary tuberculosis 1 coronary artery disease 1 hemiplegia 1 epilepsy and 2 diabetes. In addition to these one case of laryngeal cancer was disclosed by this examination. Incapacitating diseases of the subjects were sporadic and most of them could not be considered to have any effect on nasal or pulmonary functions

Previous diseases

Table 13 gives the frequencies of the previous diseases related to the symptoms and signs of the nose and upper respiratory system as reported by the subjects.

The number or frequency of previous diseases and symptoms according to table 13 was in some cases so high that statistical treatment was possible The subjects had had some degree of dyspnea in 16 %, allergic symptoms in 31 % heart symptoms in 11 % sinusitis in 24 % unconsciousness caused by head injuries in 26 % nasal injuries in 9 % chronic rhinitis in 43 % and headache in 59 %

Six of the nasal injuries (table 13) had taken place during the age of growth and eight after it The effect of injuries on the later development of the nose could not however be examined because the cases were so few None of the subjects had a nasal deformity caused by freezing burning or illness. 19 subjects had weighed at birth more than four kg 114 less than that and 29 did not know their weight at birth Two of the subjects had been delivered through a Caesarean section 155 normally and five did not know how they had been delive

Outdoor work was experienced significantly disadvantageous as far as temperature variations and the presence of impurities and chemicals in inspired air were concerned. High humidity and draught on the other hand were equally disturbing in both indoor and outdoor work.

Previous operations

Although the subjects were randomly selected none of them had had a previous septum or pyramid operation. One had had a maxillary sinus operation, polypi had been removed from two persons and four of them had had a turbinate operation. Adenoidectomy had been made in 4.9 per cent and tonsillectomy in 15.4 per cent.

Heredity

The subjects were asked about the incidence of asthma, allergic rhinitis, chronic infectious rhinitis, and heart diseases among close relatives (grandparents, parents, brothers and sisters and children) (table 12). The subjects seemed to have a very clear idea about the heart diseases of their relatives but the notes about nose troubles among the relatives were more or less guesses. Apparently only the incidence of heart diseases and asthma can be used reliably while examining intercorrelations of heredity and nasal symptoms and signs.

Table 12. The incidence of nasal, respiratory and heart diseases among close relatives (per cent)

Symptoms	Frequent	Occasional	None
Rhinitis chr	0	5	95
Rhinitis allerg	1	8	91
Asthma	3	2	75
Heart disease	1	30	58

Incapacitating diseases

Eleven of the subjects were suffering from a serious disease that obviously lowered their functional capacity. The diagnoses were: 1 multiple sclerosis, 1 pulmonary emphysema, 1 hypertension, 1 pulmonary silicosis, 1 hypothyroidism, 1 pulmonary tuberculosis, 1 coronary artery disease, 1 hemiplegia, 1 epilepsy and 2 diabetes. In addition to these one case of laryngeal cancer was disclosed by this examination. Incapacitating diseases of the subjects were sporadic and most of them could not be considered to have any effect on nasal or pulmonary functions.

Previous diseases

Table 13 gives the frequencies of the previous diseases related to the symptoms and signs of the nose and upper respiratory system as reported by the subjects.

The number or frequency of previous diseases and symptoms according to table 13 was in some cases so high that statistical treatment was possible. The subjects had had some degree of dyspnea in 16 %, allergic symptoms in 31 %, heart symptoms in 11 %, sinusitis in 24 %, unconsciousness caused by head injuries in 26 %, nasal injuries in 9 %, chronic rhinitis in 43 % and headache in 59 %.

Six of the nasal injuries (table 13) had taken place during the age of growth and eight after it. The effect of injuries on the later development of the nose could not, however, be examined because the cases were so few. None of the subjects had a nasal deformity caused by freezing, burning or illness. 19 subjects had weighed at birth more than four kg, 114 less than that and 29 did not know their weight at birth. Two of the subjects had been delivered through a Caesarean section, 155 normally and five did not know how they had been delivered.

Table 21 Appearance of the external nose (per cent)

— deformed	1
— narrow	3
— round	14
— elliptical	82

Nasal septum

When the septum was examined special attention was paid to the deviations and their relationship with the lateral wall. The location of obstructions and impactions were determined. There were no subjects with septal perforations in this study

Dislocation of the caudal end of the septum could be found in 17 % obstructing septum in 10 %, impacting septum in 14 % and considerable deviation of the septum in 11 % of the subjects (Table 22) This examination supports the view that septal deviation occurs more frequently on the left than on the right.

Table 22 Incidence of septal deformities among subjects (per cent)

Caudal septum	
— in right vestibulum	10
— in left vestibulum	7
— in the midline	83
Obstruction (16 cases)	
— anterior	6
— posterior	4
— to the right	4
— to the left	6
— no obstruction	90
Impaction (23 cases)	
— anterior	
— posterior	12
— to th right	8
— to the left	6
— to the middle turbinate	
— to the inferior turbinate	12
— no impaction	88
Septal deviation (77 cases)	
— considerabl to both sides	1
— considerabl to the right	4
— considerable to the left	6
— moderate to the right	14
— moderate to the left	23
— no apparent deviation	5.

According to this examination no correlation could be found between the most prevalent sleeping position (table 17) and presence of impaction, obstruction or considerable deviation of the septum.

The influence of septal pathology is discussed in more detail in table 23 The low incidence of nasal pathology in this material, as can be expected in a random sample, limits the validity of statistical analysis of the correlations between symptoms and signs. Regarding obstruction and impaction some comparisons were, however made with the percentages of the whole material.

Ogura s (1968) classification (page 15) of the state of obstruction in the nose has not been used in this study because the effect of separate intranasal deformities on nasal symptoms and signs has been of particular interest.

Sleeping position

Many of the subjects had a clear idea of their most prevalent (often also the only possible) sleeping position (table 17)

T a b l e 1 7 Most prevalent sleeping position of the subjects (per cent)

Skin and mucous membrane

Pathological changes in the skin of the nose were small scars in 4 9 % vascular changes *in 0 6 % atrophy in 1.9 % and dermatitis* in 2.5 % of subjects. The scars were in all cases due to a trauma In two out of *three* cases the atrophy of the skin was connected with a positive tension test.

In mucous membranes the changes were much more frequent atrophy in 14 % hypertrophy in 10 % and inflammation in 7 % of the subjects. Mucous secretion was observed in 29 and watery secretion in the noses of 9 per cent of the subjects. Notes about the state of mucous membranes were, however based on subjective opinions of the author and not on any specific examination

Appearance of the external nose

The various details of the shape and structure of the external nose, which were examined are given in table 21

Asymmetry of the nasal pyramid was found in 18 % asymmetry of the tip in 11 % abnormally *acute or obtuse naso labial angle* in 13 % and other than elliptical form of the nostrils in 18 % of the subjects (table 21) *In addition to that* the nostrils were asymmetrical in 12 per cent the columella was hanging in 5 retracted in 2 short in 1 long in 3 and oblique in 3 per cent of the subjects

Table 21 Appearance of the external nose (per cent)

Profile of the nose	
— fairly straight	4
— concave	43

— 85 95°	87
— obtuse	9
Nostrils	
— deformed	1
— narrow	3
— round	14
— elliptical	82

Nasal septum

When the septum was examined special attention was paid to the deviations and their relationship with the lateral wall. The location of obstructions and impactions were determined. There were no subjects with septal perforations in this study.

Dislocation of the caudal end of the septum could be found in 17 % obstructing septum in 10 % impacting septum in 14 % and considerable deviation of the septum in 11 % of the subjects (Table 22). This examination supports the view that septal deviation occurs more frequently on the left than on the right.

Table 22 Incidence of septal deformities among subjects (per cent)

Caudal septum	
— in right vestibulum	10
— in left vestibulum	7
— in the midline	83
Obstruction (16 cases)	
— anterior	6
— posterior	4
— to the right	4
— to the left	6
— no obstruction	90
Impaction (23 cases)	
— anterior	2
— posterior	12
— t the right	8
— to the left	6
— to the middle turbinate	2
— to the inferior turbinate	12
— no impaction	86
Septal deviation (77 cases)	
— considerable to both sides	1
— considerabl to the right	4
— considerable to the left	6
— moderate to the right	14
— moderate to the left	23
— no apparent deviation	52

According to this examination no correlation could be found between the most prevalent sleeping position (table 17) and presence of impaction, obstruction or considerable deviation of the septum.

The influence of septal pathology is discussed in more detail in table 23. The low incidence of nasal pathology in this material, as can be expected in a random sample limits the validity of statistical analysis of the correlations between symptoms and signs. Regarding obstruction and impaction some comparisons were however made with the percentages of the whole material.

Ogura's (1968) classification (page 15) of the state of obstruction in the nose has not been used in this study because the effect of separate intranasal deformities on nasal symptoms and signs has been of particular interest.

Table 23 Percentage incidence of certain symptoms and signs in the subjects with obstruction or impaction in the nose compared to the incidence in the whole material [1])

	Obstruction N = 16	Impaction N = 23	Whole material N = 162

[1]) *The degree of significance is based on statistical comparisons* (Alameri *et al* 1961) *between obstruction and whole material or impaction and whole material*

Obstruction of the nose seems to produce a significant tendency to continuous rhinitis and snoring. Mid-cycle rest is typical of impaction nose and flat top deformity of the pressure curve is often connected with obstruction. The statistical significance of these findings is given in table 23. The relation of obstruction and impaction to maximal nasal ventilation and nasal breathing pressure is given in table 33.

Vestibulum. Valve-area

The density of vibrissae in the vestibulum and the structure of the valve area were examined in all subjects. In addition the mobility of the alae and the valve were estimated during nasal breathing. In five cases there was a marked deformity in the upper lateral cartilage. The results of valvular and vestibular examinations are given in table 24.

Table 24. Structural and functional evaluation of the vestibulum and valve area (per cent)

Vibrissae	
— abundant	11
— average	60
— scarce	29
Alar insufficiency	
— present	9
— absent	91
Valve area	
— obstruction	6
— normal	92
— ballooning	2
Valvular mobility	
— stiff	10
— ordinary	59
— very mobile	31

Alar or valvular mobility had no significant correlation to flow or pressure values. Only the frequency during maximal nasal ventilation tends to be higher when valve is mobile (on .05 significant level correlation). The flexibility of the valve is obviously a reason for high frequency during maximal nasal ventilation.

Cul-de sac was wide in nine per cent and very small in 19 per cent and could be considered normal in all other cases. Wide cul-de sac had a positive correlation (on .05 significant level) with sense of smell (trigeminal sensation and cocoa) and negative correlation (on .05 significant level) to nasal pains. According to this examination a wide cul-de sac obviously directs the air currents more effectively to the olfactory epithelium.

Nasal airway

Obstructing polyps were found in 3 and small polyps in 0.6 per cent of the cases. 38 per cent had swollen turbinates. There were no cases of atrophy of turbinates or intranasal synechia. None of the subjects had cleft palate, choanal polyps or adenoid hypertrophy. During the examination mainly oral breathing was observed in 14 per cent of the subjects, two of the subjects had rhinolalia clausa and four had other phonetic disturbances. According to the clinical record 15 per cent of the subjects were mouth breathers.

Dependent variables

Symptoms

In table 25 the incidence is recorded of eleven symptoms considered significant for the functions of the nose or lungs or that may be caused by disturbances in their functions or structures.

Table 25. Incidence of symptoms of the upper respiratory system (per cent)

Symptoms	Frequent	Occasional	Never
Nasal pains	2	10	88

Table 33 Relationship of septal deformity with maximal nasal ventilation (V_M) and nasal breathing pressure while subject is lying supine without nasal medication

	Obstruction		Impaction		Whole material	
N	10	8	13	10	71	91
Sex	Men	Women	Men	Women	Men	Women
V_M l/min (mean)	56 ±12.15	40 ± 7.97	60 ±22.60	43 ±10.70	66 ±19.66	42 ±13.21
Breathing pressure mm/H_2O — inspiration (mean) dx	12.6 ±13.26	12.0 ± 7.87	8.6 ± 3.18	7.0 ± 1.56	9.1 ± 7.89	7.8 ±4.14
— inspiration (mean) sin	15.3 ±14.94	11.3 ± 8.71	9.5 ± 3.98	6.6 ± 2.15	9.8 ± 7.05	7.7 ± 3.90
— expiration (mean) dx	[illegible] ± 7.45	9.5 ± 4.23	9.2 ± 4.25	6.2 ± 1.84	8.7 ± 6.14	[illegible] ± 3.48
— expiration (mean) sin	13.2 ±13.43	8.0 ± 3.46	10.2 ± 4.48	5.8 ± 2.27	10.1 ± 6.57	6.8 ± 2.87

No significant differences could be found when results of obstruction or impaction groups (table 33) were compared to those of whole material.

Pressure readings are a little smaller for women. There is no remarkable difference between left and right side readings. When examining the differences of the mean pressures (only results for all the subjects included) according to the tables above, a certain regularity can be seen between different groups

It must be taken into consideration that upper nostril lower nostril and dilated nostril values are also taken after shrinkage of mucous membranes In side positions the congestion of turbinates has no influence on the results. The differences between the upper and lower nostrils are caused by the movements of the valve.

Co-operation with the subjects was good with three exceptions. Because of a great number of irregularities in breathing pressures one curve could not be interpreted In ten cases minor irregularities occured.

When examining the shape of rhinograms obvious flat top deformity could be seen in twelve cases. Mid cycle rest was also found in twelve cases.

Flow tests

Frequency and volume readings of flow measuring are given separately for men and women in table 34 In volume results no age correlation could be found but a positive height correlation (on 0.5 significant level) was noted among men Breathing frequencies at rest, after exercise, and during maximal nasal ventilation were about the same in both sexes. Although the breathing frequencies were nearly equal at rest and after standardized exercise, the volume of breathing was almost doubled by exercise. No significant differences could be found in volumes at rest and after exercise between different sexes, but the mean volume of maximal nasal ventilation was considerably bigger among men.

Determination of limits of normal pressure and flow values

In table 35 are given 50 60 and 80 per cent limits for pressure and flow readings obtained by rhinomanometry The mean values of 4 5 successive breaths are included, the subject is lying supine.

Table 34 Mean frequencies (resp./min) and volumes (l/min) of the nasal ventilation during flow test and standard deviations of the readings[1])

DISCUSSION

The relation of nasal structure to its function and the role of the nose for the whole organism has been emphatically discussed in a number of papers and lectures by the group of nasal surgeons of the American Rhinologic Society (Williams, 1956 Cottle et al, 1958 Ogura, 1970 Hinderer 1971) and the European Rhinologic Society (Stoksted, 1953 Drettner 1970 Kortekangas, 1972). This study has been stimulated by the opinions given there and an attempt to estimate the prevalence of nasal disorders and nasal symptoms among the adult population in general has been incorporated. The questions relevant to this study are discussed in detail below

1 *Equal interval* sampling from the official register of the town of Kotka (only inhabitants from 25 to 50 years accepted) has given a representative sample of the inhabitants of the city This has been proved by the following facts different social groups were equally well represented, the working conditions of the subjects corresponded surprisingly well to those obtained by Saari (197*) and Lehto *et al* (197) the relation of the male and female subjects of this study was equal with the relation in the whole city Also the vitalogram examination (table 34) confirms that the material is unselected as far as pulmonary function is concerned and the same applies obviously also to other functional aspects, for the values of vital capacity and maximal pulmonary minute volume corresponded astonishingly well to the results of the nomogram

It can be considered a good result that over 80 per cent of the randomly selected subjects attended the examination. One third of those who did not attend (19 per cent of the whole sample) had an acceptable reason for their absence. Material selected in this way cannot be considered to have any special features regarding the nose. This is strongly supported by the fact that there were no cases of previous septum or pyramid operation.

2 The percentages of certain clinical notes in this study can be used as a basis for determining the incidence of nasal disorders among the adult population in general. As a sign of disturbed nasal function mouth breathing was seen in 14 per cent of all the subjects. Structural disproportions of the nose can produce a positive reaction to the tension test (25 per cent in this study) It can be assumed that changes in the skin (10 per cent) in the mucose membranes (31 per cent) and increases in the amount of nasal secretion (38 per cent) are connected to certain pathological states of the nose. In the course of this study a large number of structural deformities of the nose were revealed deformity of the external pyramid (18 per cent) deformity of the tip (11 per cent) deformity of the columella (30 per cent) deformity of the nostrils (18 per cent) and deformity (impaction, obstruction or considerable deviation) of the septum (26 per cent) Most of these findings can be considered to be independent signs of the pathological state of the nose. Thus it can be concluded that the mean of the percentages mentioned above (22 per cent) roughly corresponds also to the incidence of functional disorders in the noses of the test subjects. From this statement can further

pine position of test subjects was selected to make it easy to find equal condition for every subject. This position also made it possible to examine the effect of the valve on the breathing pressure when the head of the subject was alternately turned so that right nostril or left nostril was up. In side positions the effect of the congestion was eliminated by medication.

It seems to be difficult to check whether the test subject is breathing normally. Rather often forced breathing started as soon as the nozzle was in place. In these cases the test subject was asked to relax and the test was repeated. The pressures and minute volumes, however, varied a lot from person to person, often without any obvious reason. Therefore maximum nasal ventilation was selected from the various possible test methods. This study seemed to show a great difference in the incidence of significant correlations of maximal nasal ventilation between men and women. This can be explained by the fact that it was most important for men to gain good functional results, and because of that they got results which were obviously very near to their real maximum. The correlations for male subjects are therefore more reliable than those for female subjects.

Because the material is relatively small and comprised of normal subjects, it was considered to be justified to use quartile division (25 % — 50 % — 25 %) in examining nasal functions. If the corresponding variables had been based on an assumed degree of nasal disorders (e.g. 10 % — 80 % — 10 %) more correlations would certainly have been obtained, but occasional extremes of value would probably have become too significant.

5. In this study the subjects were lying supine during the pressure measurings. As stated by Rundcrantz (1964) changing the posture of the subject from sitting to supine position did not cause any significant increase in air flow resistance in normal cases. Among allergic patients, however, the resistance increased markedly within a few minutes. The supine position is firm and stable and the subjects are well relaxed, which makes it easier to achieve standardized conditions. Relaxation probably also makes the subject breathe quietly without hyperventilation. Thus the results of supine measurings can be compared with the results obtained by Cottle (1965) and Kortekangas (1972) in sitting subjects.

When trying to construct the norms for breathing pressures and flow readings, the limiting values of the middlemost 50, 60 and 80 per cent were examined (tables 35 and 36). As far as the pressure values were concerned, the limits for 80 per cent seemed to represent the limits for normal function, because when moving from the limits of 60 per cent to those of 80 per cent, the deviation of results was relatively slightly bigger than when moving from the limits of 50 per cent to those of 60 per cent, in other words occasional extremes of value begin to have some effect on the results. In flow values the same effect can be seen, so perhaps limiting values of 80 per cent give the best limits for what can be described as normal. Norms for the pressure of nasal respiration are thus (mm/H_2O)

Inspiration	men	women
right nostril	4.5—14.3	3.5—12
left nostril	4.5—15.5	3.5—11.9
Expiration		
right nostril	3.4—13.3	2.7—10.4
left nostril	3.8—14.8	2.5—10.0

Norms for maximal nasal ventilation (l/min) are for men 37.2—99.0 and for women 23.4—59.0.

If the results of maximal nasal ventilation are compared with vitalogram results, it can be seen that the mean volume of maximal nasal ventilation for men was 44

be concluded that about 20 per cent of the results obtained by rhinomanometry are in the range of extreme values that can be considered abnormal

3 According to the clinical nasal index nearly all the noses in this study can unquestionably be classified to the leptorrhinians (table 20) Only 7 4 per cent range to any other group Earlier studies using cephalometric indices suggest that in Finland 47—96 per cent of the noses of the native population are of the leptorrhinian type (Roschier 1931 Arho 1934 Pesonen, 1935 and 1937 Lofgren 1937 Mustakallio and Telkka 1951 and Telkka 1953)

On the other hand only 43 per cent according to the tip index and 44 per cent according to the salience indices belonged to the leptorrhinians. Can this be explained by some Special characteristic of the noses examined? During the last decades the mean height of the population has increased, as stated also in this study No correlation could be found between height and clinical nasal index or tip index. On the other hand a high significant positive correlation was found between height and salience indices This is apparently explained by the increase in the prominence of the bony pyramid among tall people. According to this study the profile of the nose was only in eight per cent convex, and in the studies by Mustakallio and Telkka (1951) and Arho (1934) the profile of the Finnish nose was convex in 4 9—31 6 per cent. Although the bony pyramid of the Finnish nose is exceptionally low the high salience readings can be explained by the facts that the base of the nose is rather small (nostrils are elliptical or narrow in 85 per cent of the subjects) and rounded or quadratic (tip index values are relatively high)

With only one exception all noses which according to the tip index belonged to the leptorrhinians belonged to this group also according to the clinical nasal index

To conclude, the average nose according to this study belongs to the leptorrhinians, its profile is concave or straight, the tip index and salience indices are relatively high owing to the small rounded or quadratic base of the nose. The nostrils are mainly elliptical

4 The reliability of most testing methods in this study is based on subjective conception (evaluation of clinical findings, tension test) and accuracy (measuring indices, photography) of the author and making the test subject spontaneous and co-operative (olfactory trigeminal vitalogram and rhinomanometric testings) Co-operation was found to be good in 98 per cent during rhinomanometric examinations. As a result of careful planning of the test methods no changes had to be made in the order or manner of performing the tests.

Indices obtained by photography were regularly smaller than those obtained from nasal measurings (table 18) To increase the reliability of the indices measured from slides the points of measuring should be marked on the skin before photography Color slides proved to be of special importance when notes about the structure or appearance of the nose were checked afterwards

The amount of positive olfactory and trigeminal sensations was probably diminished because the mucous membranes were not shrunk before the testing of the acuity of the smell Thus the results obtained do not correspond only to the state of the olfactory epithelium and its pathways but also to the state of the congestive tissues inside the nose. The test substances were familiar to everybody and they were also quite strong stimulants and could easily be recognized if the condition of the nose was normal

The reliability of vitalogram tests was confirmed by the fact that the results obtained by it corresponded well to the nomograms. During rhinomanometric examinations su

pine position of test subjects was selected to make it easy to find equal condition for every subject. This position also made it possible to examine the effect of the valve on the breathing pressure when the head of the subject was alternately turned so that right nostril or left nostril was up. In side positions the effect of the congestion was eliminated by medication.

It seems to be difficult to check whether the test subject is breathing normally. Rather often forced breathing started as soon as the nozzle was in place. In these cases the test subject was asked to relax and the test was repeated. The pressures and minute volumes, however, varied a lot from person to person, often without any obvious reason. Therefore maximum nasal ventilation was selected from the various possible test methods. This study seemed to show a great difference in the incidence of significant correlations of maximal nasal ventilation between men and women. This can be explained by the fact that it was most important for men to gain good functional results, and because of that they got results which were obviously very near to their real maximum. The correlations for male subjects are therefore more reliable than those for female subjects.

Because the material is relatively small and comprised of normal subjects, it was considered to be justified to use quartile division (25 % — 50 % — 25 %) in examining nasal functions. If the corresponding variables had been based on an assumed degree of nasal disorders (e.g. 10 % — 80 % — 10 %) more correlations would certainly have been obtained, but occasional extremes of value would probably have become too significant.

5. In this study the subjects were lying supine during the pressure measurings. As stated by Rundcrantz (1964) changing the posture of the subject from sitting to supine position did not cause any significant increase in air flow resistance in normal cases. Among allergic patients, however, the resistance increased markedly within a few minutes. The supine position is firm and stable and the subjects are well relaxed, which makes it easier to achieve standardized conditions. Relaxation probably also makes the subject breathe quietly without hyperventilation. Thus the results of supine measurings can be compared with the results obtained by Cottle (1963) and Kortekangas (1972) in sitting subjects.

When trying to construct the norms for breathing pressures and flow readings, the limiting values of the middlemost 50, 60 and 80 per cent were examined (tables 35 and 36). As far as the pressure values were concerned, the limits for 80 per cent seemed to represent the limits for normal function, because when moving from the limits of 60 per cent to those of 80 per cent, the deviation of results was relatively slightly bigger than when moving from the limits of 50 per cent to those of 60 per cent, in other words occasional extremes of value begin to have some effect on the results. In flow values the same effect can be seen, so perhaps limiting values of 80 per cent give the best limits for what can be described as normal. Norms for the pressure of nasal respiration are thus (mm/H_2O)

Inspiration	men	women
right nostril	4.5—14.8	3.5—12.2
left nostril	4.5—15.8	5.5—11.9
Expiration		
right nostril	3.4—13.3	2.7—10.4
left nostril	3.8—14.0	2.5—10.0

Norms for maximal nasal ventilation (l/min) are for men 37.2—92.0 and for women 23.4—59.0.

If the results of maximal nasal ventilation are compared with vitalogram results, it can be seen that the mean volume of maximal nasal ventilation for men was 44

be concluded that about 20 per cent of the results obtained by rhinomanometry are in the range of extreme values that can be considered abnormal

3 According to the clinical nasal index nearly all the noses in this study can unquestionably be classified to the leptorrhinians (table 20) Only 7 4 per cent range to any other group Earlier studies using cephalometric indices suggest that in Finland 47—96 per cent of the noses of the native population are of the leptorrhinian type (Roschier 1931 Arho 1934 Pesonen 1935 and 1937 Lofgren, 1937 Mustakallio and Telkka 1951 and Telkka 1953)

On the other hand only 43 per cent according to the tip index and 44 per cent according to the salience indices belonged to the leptorrhinians Can this be explained by some Special characteristic of the noses examined? During the last decades the mean height of the population has increased as stated also in this study No correlation could be found between height and clinical nasal index or tip index On the other hand a high significant positive correlation was found between height and salience indices This is apparently explained by the increase in the prominence of the bony pyramid among tall people. According to this study the profile of the nose was only in eight per cent convex, and in the studies by Mustakallio and Telkka (1951) and Arho (1934) the profile of the Finnish nose was convex in 4 9—31 6 per cent Although the bony pyramid of the Finnish nose is exceptionally low the high salience readings can be explained by the facts that the base of the nose is rather small (nostrils are elliptical or narrow in 85 per cent of the subjects) and rounded or quadratic (tip index values are relatively high)

With only one exception all noses which according to the tip index belonged to the leptorrhinians belonged to this group also according to the clinical nasal index.

To conclude the average nose according to this study belongs to the leptorrhinians, its profile is concave or straight the tip index and salience indices are relatively high owing to the small rounded or quadratic base of the nose. The nostrils are mainly elliptical

4 The reliability of most testing methods in this study is based on subjective conception (evaluation of clinical findings, tension test) and accuracy (measuring indices, photography) of the author and making the test subject spontaneous and co-operative (olfactory trigeminal vitalogram and rhinomanometric testings) Co-operation was found to be good in 98 per cent during rhinomanometric examinations. As a result of careful planning of the test methods no changes had to be made in the order or manner of performing the tests.

Indices obtained by photography were regularly smaller than those obtained from nasal measurings (table 18) To increase the reliability of the indices measured from slides, the points of measuring should be marked on the skin before photography Color slides proved to be of special importance when notes about the structure or appearance of the nose were checked afterwards

The amount of positive olfactory and trigeminal sensations was probably diminished because the mucous membranes were not shrunk before the testing of the acuity of the smell Thus the results obtained do not correspond only to the state of the olfactory epithelium and its pathways but also to the state of the congestive tissues inside the nose The test substances were familiar to everybody and they were also quite strong stimulants and could easily be recognized if the condition of the nose was normal

The reliability of vitalogram tests was confirmed by the fact that the results obtained by it corresponded well to the nomograms. During rhinomanometric examinations su

ine position of test subjects was selected to make it easy to find equal condition for every subject. This position also made it possible to examine the effect of the valve on the breathing pressure when the head of the subject was alternately turned so that right nostril or left nostril was up. In side positions the effect of the congestion was eliminated by medication.

It seems to be difficult to check whether the test subject is breathing normally. Rather often forced breathing started as soon as the nozzle was in place. In these cases the test subject was asked to relax and the test was repeated. The pressures and minute volumes, however, varied a lot from person to person, often without any obvious reason. Therefore maximum nasal ventilation was selected from the various possible test methods. This study seemed to show a great difference in the incidence of significant correlations of maximal nasal ventilation between men and women. This can be explained by the fact that it was most important for men to gain good functional results, and because of that they got results which were obviously very near to their real maximum. The correlations for male subjects are therefore more reliable than those for female subjects.

Because the material is relatively small and comprised of normal subjects, it was considered to be justified to use quartile division (25 % — 50 % — 25 %) in examining nasal functions. If the corresponding variables had been based on an assumed degree of nasal disorders (e.g. 10 % — 80 % — 10 %) more correlations would certainly have been obtained, but occasional extremes of value would probably have become too significant.

5. In this study the subjects were lying supine during the pressure measurings. As stated by Rundcrantz (1964) changing the posture of the subject from sitting to supine position did not cause any significant increase in air flow resistance in normal cases. Among allergic patients however the resistance increased markedly within a few minutes. The supine position is firm and stable and the subjects are well relaxed, which makes it easier to achieve standardized conditions. Relaxation probably also makes the subject breathe quietly without hyperventilation. Thus the results of supine measurings can be compared with the results obtained by Cottle (1963) and Kortekangas (1972) in sitting subjects.

When trying to construct the norms for breathing pressures and flow readings, the limiting values of the middlemost 50, 60 and 80 per cent were examined (tables 35 and 36). As far as the pressure values were concerned the limits for 60 per cent seemed to represent the limits for normal function, because when moving from the limits of 60 per cent to those of 80 per cent, the deviation of results was relatively slightly bigger than when moving from the limits of 50 per cent to those of 60 per cent, in other words occasional extremes of value begin to have some effect on the results. In flow values the same effect can be seen, so perhaps *limiting values of 80* per cent give the best limits for what can be described as normal. Norms for the pressure of nasal respiration are thus (mm/H_2O)

Inspiration	men	women
right nostril	4.5—14.3	3.5—12.2
left nostril	4.5—15.3	3.5—11.9
Expiration		
right nostril	3.4—13.3	2.7—10.4
left nostril	3.8—14.9	2.3—10.0

Norms for maximal nasal ventilation (*l/min*) are for men 87.2—92.0 and for women [illegible]4—59.0.

If the results of maximal nasal ventilation are compared with vitalogram results, it can be seen that the mean volume of maximal nasal ventilation for men was 44

per cent and for women 42 per cent of the mean volume of maximal pulmonary ventilation.

8 Correlations of nasal symptoms and signs are discussed here according to the frames of reference. Symptom complex was formed of 5 items which were selected on the basis of intercorrelations from 11 nasal symptoms Olfactory trigeminal pressure, and flow complexes were also formed using available items to represent nasal signs in correlation studies. Symptom complex revealed as expected significant positive correlations as to chronic rhinitis deviation of the septum prominent nose, and allergy (table 39) Surprisingly enough a high positive significance could be found between symptom complex and coronary artery disease There were some environmental circumstances which significantly coincided with nasal symptoms. According to this study smoking outdoor work, severe head injury and heredity (asthma and heart diseases among close relatives) had significant positive correlations to the symptom complex A previous tonsillectomy on the other hand had a significant negative correlation to nasal symptoms There was no evidence in this study of oral contraceptives having any effect on the occurence of nasal symptoms

It was possible in this study to trace a significant degree of coincidence between smoking chronic rhinitis working conditions and the sense of smell (table 40) There was a significant correlation between olfactory acuity and the deviation of the septum This is explained by the fact that septum deviation in many cases obviously directs air currents away from the olfactory epithelium *Also the structure of the base* of the nose had some effect on the direction of air currents because the tip index had a significant correlation with olfactory acuity i.e. the increase in the tip index values made the olfactory acuity better

Leigh (1943) Sumner (1964) and Caruso *et al* (1969) stated that the sense of smell is weakened by earlier head injury According to this study a severe head injury had a significant correlation only with trigeminal sensitivity According to Strauss (1930) the sense of smell was weakened when the subject was getting older In this study a significant lowering in olfactory acuity was found with advancing age, but no significant coincidence was found with trigeminal acuity According to v Dishoek (1963) allergy causes hyposmia this result was, however not confirmed in this study

The fact that no significant correlations could be found in this study between nasal breathing pressures and deviations or deformities of the septum can be explained by rather big variations in the normal values of breathing pressures. As stated by Cottle (1968) marked increase in breathing pressure practically always means a nasal obstruction In this study allergy which obviously means swollen turbinates, coincided significantly with breathing pressure. Breathing pressure had also significant correlation with the frequency of maximal nasal ventilation In other words obstruction of the nose causes a high breathing frequency during maximal nasal ventilation. An obstructed nose obviously leads to forced nasal breathing because nasal breathing pressure correlated significantly with the volume of nasal ventilation at rest and after exercise.

No significant coincidence could be found in this study between weight at birth and septum deformities Also Jeppesen and Winfeld (1972) could not find any relationship between weight at birth and the number of *septal dislocations According to this study* (table 44) tension nose corralated significantly among men with the salience index and among women with the tip index. Hinderer (1971) also found relationship between structural properties and tension of the nose

According to this study only chronic rhinitis, snoring and trigeminal sensitivity correlated significantly with septal obstruction. The subjects with septal obstruction also had considerably more frequently heart symptoms, mouth breathing sinusitis, and *sneezing* but the differences did not reach the level of significance.

In rhinogram the mid-cycle rest deformity correlated significantly with the impaction of the septum. In cases with impaction continuous headache was a common finding whereas the flat top was found relatively seldom. The incidence of both mid-cycle rest and flat top on the pressure curves in relation to obstruction or impaction of the septum was the opposite of what was found by Cottle (1968). Obstruction seems to decrease maximal nasal ventilation and increase the pressure of normal breathing. No significant relationship could however be found in this examination, probably because of the small number of cases investigated (table 25).

On examination of the intercorrelations of *dependent variables* (*table 45*) a significant relationship was found between nasal symptoms and olfactory and trigeminal sensitivity. The symptom complex correlated significantly with maximal nasal ventilation and maximal minute volume of the lungs. There was a correlation of high significance between olfactory and trigeminal sensitivity. The tension of the nose had a significant relationship with trigeminal acuity. The volume of maximal nasal ventilation had a positive significant correlation with the maximal minute volume of the lungs and the vital capacity of the lungs. The minute volume and the vital capacity of the lungs had a intercorrelation of high significance.

per cent and for women 42 per cent of the *mean volume of maximal pulmonary ventilation*

6 *Correlations of nasal symptoms and signs are discussed here according to the* frames of reference. Symptom complex was formed of 5 items which were selected on the basis of intercorrelations from 11 nasal symptoms Olfactory trigeminal pressure, and flow complexes were also formed using available items to represent nasal signs in correlation studies. *Symptom complex* revealed as expected significant positive correlations as to chronic rhinitis deviation of *the septum prominent nose,* and *allergy* (table 39) Surprisingly enough a high positive significance could be found between symptom complex and coronary artery disease. There were some environmental circumstances which significantly coincided with nasal symptoms According to this study smoking outdoor work severe head *injury* and *heredity (asthma and heart* diseases among close relatives) had *significant positive correlations to the symptom* complex A previous *tonsillectomy* on the other hand had a significant *negative* correlation to nasal symptoms There was no evidence in this study of oral contraceptives having any effect on the occurence of nasal symptoms

It was possible in this study to trace a significant degree of coincidence between smoking chronic rhinitis working conditions and the sense of smell (table 40) There was a significant correlation between olfactory acuity and the deviation of the *septum This is explained by the fact that* septum deviation in many cases obviously directs air currents away from the olfactory epithelium Also the structure of the base of the nose had some effect on the direction of air currents because the tip index had a significant correlation with olfactory *acuity i e the increase in the tip index* values made the olfactory acuity better

Leigh (1943) Sumner (1964) and Caruso *et al (1969)* stated that the sense of smell is weakened by earlier head injury According to this study a severe head injury had a significant correlation only with trigeminal sensitivity According to Strauss (1930) the sense of smell was weakened when the subject was getting older In this study a significant *lowering in olfactory acuity was found with advancing age but no significant* coincidence was found with trigeminal acuity According to v Dishoek (1963) allergy causes hyposmia this result was, however not confirmed in this study

The fact that no significant correlations could be found in this study between nasal breathing pressures and deviations or deformities of the septum can be explained by rather big variations in the normal values of breathing pressures As stated by Cottle (1968) marked increase in breathing pressure practically always means a nasal obstruction In this study allergy which obviously means swollen turbinates, coincided *significantly with breathing pressure. Breathing pressure had also significant* correlation with the frequency of maximal *nasal ventilation. In other words obstruction of the nose causes a high breathing frequency* during maximal nasal ventilation An obstructed nose obviously leads to *forced nasal breathing* because *nasal* breathing pressure correlated significantly with the volume of nasal ventilation at rest and after exercise

No significant coincidence could be found in this study between weight at birth and *septum deformities* Also Jeppesen and Winfeld (1972) could not find any relationship between weight at birth and the number of septal dislocations. According to this study (table 44) tension nose corralated significantly among men with the salience index and among women with the tip index Hinderer (1971) also found relationship between structural properties and tension of the nose.

SUMMARY

Two hundred inhabitants of Kotka, whose names had been obtained by equal interval sampling were invited to come for an examination of the nose and upper respiratory system. Results of nasal signs investigated and answers to a number of inquiries regarding nasal and related symptoms, environmental circumstances e.t.c. were available for 162 persons. The representativeness of this group was proved by the facts that different social groups, both sexes and variations in working conditions were represented according to the expectations and that the results obtained by vitalogram corresponded exactly to the nomogram.

As the subjects were picked out by an equal interval sampling it was to be expected that they would mainly be people in a normal state of health. Structural changes were found in different parts of their noses, which on average could be considered abnormal in 20 per cent.

Anthropologically 92.6 per cent of the subjects belonged to the leptorrhinians according to the clinical nasal index. The bases of the noses examined were obviously different from the typical leptorrhinian nose, because according to the tip index only 44 per cent range to this group. Only 6 per cent of the noses examined had convex profiles. All the subjects who had a convex profile of the nose belonged to the leptorrhinians according to the clinical nasal index. With only one exception all noses which according to the tip index belonged to the leptorrhinians, belonged to this group also according to the clinical nasal index.

Quartile division of the functional results was used for correlation studies to avoid extra correlations by extremes of value. Cooperation was good with the subjects in 98 per cent during rhinomanometric examinations.

The norms for the rhinomanometric results were based on the incidence of nasal disorders (about 20 per cent) and on the fact that the limits for 80 per cent seemed to represent the point after which occasional extremes of value began to have some effect on the results. Limits for normal breathing pressures changed among men from 3.4 to 15.5 mm/H_2O and among women from 2.5 to 12.2 mm/H_2O. The mean of the maximal nasal ventilation was for men 44 per cent and for women 42 per cent of the mean volume of the maximal pulmonary ventilation. The limits for normal maximal nasal ventilation were for men from 37.2 to 92.0 and for women from 23.4 to 59.0 l/min.

Special attention was paid to studying correlations between nasal symptoms and signs and numerous environmental circumstances called background variables. Based on the intercorrelations of 11 nasal symptoms five of these (dryness of throat, sneezing, post nasal discharge, snoring and mouth breathing) were selected to represent all the symptoms in correlation studies as a symptom complex. Also of nasal signs were formed combined variables which respectively were called olfactory, trigeminal, pressure, and flow complexes.

The nasal symptom complex correlated significantly to a number of background variables. Significantly higher incidence of nasal symptoms occurred in subjects with chronic rhinitis, septal deviation, prominent nose, allergy, coronary artery disease,

smoking outdoor work and severe head injury Significantly lower incidence of nasal symptoms was found in subjects whose tonsils had been removed

Significant relationships could be found in this study between olfactory acuity and smoking chronic rhinitis outdoor work inconvenience at work deviation of the septum tip index, and the age of the subject. There was some difference in the correlations of trigeminal acuity which had significant correlations to smoking chronic rhinitis outdoor work inconvenience at work, and severe head injury

No significant correlations could be found between nasal breathing pressure and deviations or deformities of the septum obviously *because of rather big variations* in the normal values of the pressure. If the pressure was raised, the volume of nasal breathing was significantly increased at rest and after exercise

Obstruction of the nose correlated significantly only with chronic rhinitis snoring and trigeminal acuity in this study Impaction of the septum correlated significantly with mid cycle deformity of the rhinogram

ACKNOWLEDGMENTS

I wish to express my gratitude to my former teacher *Associate Professor A E Kortekangas* He encouraged me to start this study and he also gave me a great deal of valuable advice in connection with the planning and realization of this project.

I am also grateful to Professor Otto H Meurman, M D Head of the Department of Otolaryngology University of Turku who has followed my work with great interest and courtesy throughout its course.

My sincere thanks are due to my present chief Kari Pulkkinen M.D Head of the Department of Otolaryngology in the Central Hospital of Kotka who has made it possible for me to carry out this study in his clinic and has also offered me valuable advice after reading the manuscript

I am most grateful to my brother Docent *Ilkka Vainio-Mattila D.Agr.Sc, M.Sc., Di*rector of the Marketing Research Institute of the Pellervo Society in Helsinki who has shown great interest in my research at all its stages. His ideas and criticisms have been essential in handling the problems, especially *statistical ones* of this work.

My gratitude is particularly due to my wife, Pirkko Vainio-Mattila B A Sworn Translator and Mr Anthony Jenkins B.A. for their co-operation in translating this thesis into English

Finally I wish to thank Suomen Lääketieteen Saatio (Orionin Tieteellinen Tutkimusrahasto) Korvatautien tutkimussaatio Suomen Kulttuurirahasto and Kymenlaakson Rahasto for their financial support

UPPSALA 1974

Introduction

The headaches studied here are the common troublesome and frequently recurrent headaches—sustained muscle contraction headaches. While these are known to be caused by noxious pathology in the head and neck and also to occur after head injury those dealt with here are those occurring spontaneously. As a cause of these Swanson (1971) suggests conceptions such as emotional tension states anxiety frustration or depression. He also says these headaches are due to contraction of skeletal muscles about the face scalp and neck and also that concurrent vasodilatation of the associated cranial arteries frequently contributes to the irritability of the involved muscles and to the headache. He says tinnitus dizziness and lacrimation occur with the headaches and that these may be produced or increased by pressure on the contracted muscles. No treatment appears to be of any avail. Ostfeld (1963) says that in many cases of migraine (77 out of 114 patients) a so-called "background" headache appears which he diagnosed clinically as skeletal muscle contraction headache. It is useful to state here that Schiller & Hedberg (1960) finding PN in a group they classified as "anxiety" and also observing that the majority of patients in this group suffered from vascular or tension (muscle contraction) headaches also wonder about the relationship of PN both to anxiety and to the headache and make the admission that they are open to criticism because they failed to give a clear-cut answer to the question whether PN in this group ("anxiety") is a psychosomatic or a somatopsychic manifestation.

In this study the muscle contraction headaches have been diagnosed clinically from their vice-like or gripping nature gradual onset and increase and very frequent recurrence, differentiating them thus from the vascular headaches (Graham, 1963) which have a throbbing quality sudden onset with or without aura, and less frequent recurrence. He also says that the headache in the muscle contraction type is really a constant one (with frequent exacerbations).

On the basis of a certain neuro-otological conception and a minor otological interference it has become possible to cure completely 100 consecutive cases of muscle contraction headaches and thus come to a conclusion on their mechanism of production. Two new signs are here described in relation to these headaches and there is reason to believe that these are applicable to the Vascular Headaches also. Light is also shed on the PN that accompanies these headaches since in this work the PN has been made to disappear in a 100 cases.

Theory

Positional nystagmus (PN)

The PN seen in these cases was a brisk, sustained (right through the maintenance of the Position) non-fatigable non-paroxysmal horizontal first-degree nystagmus of the central type (Edwards 1971). Since it follows from what will be said in this article that it

have used the electron microscope and histochemical methods to detect the presence of nerve fibres showing acetylcholinesterase (AChE) activity in the non-acoustic and acoustic labyrinth of animals. Iurato et al (1971) have shown efferent nerve fibres (unmyelinated) with AChE activity in the vestibular sensory areas of the chinchilla. In this species the efferent fibres appear to take a separate-course from the brain stem along with the afferent fibres Terayama & Yamamoto (1971) studying the olivo-cochlear bundle in the guinea pig, found efferent endings and preterminal fibres inside the organ of Corti and state that their relationship to the myelinated and unmyelinated efferent fibres outside the organ still remains unknown It is here advanced that parasympathetic efferent nerve terminals are to be found in the human inner ear both non-acoustic and acoustic The experimental investigations in animals would appear to speak in support of this view rather than controvert it. The work of Ishii (1971) in the rat appears to show that these fibres could not have found their way into the inner ear along the blood vessels though he found AChE activity in the stria vascularis and spiral ligament behind the external sulcus and the author here and elsewhere makes the serious claim that the LB to the CT is an anatomical entity

Regarding these LCAs it will be postulated that they lie in the middle of the superior temporal gyrus of each side (Fig. 2) While there are many reasons for saying this those of immediate concern are that they must be in close association with the cortical vestibular projection areas on each side which Behrman & Wyke (1958) after studying all the relevant evidence conclude as extending forward from behind the primary acoustic area to lie below and lateral to the latter in the superior temporal gyrus There is also the reason that Carmichael et al (1954) have shown that a destructive lesion in the posterior part of the temporal lobe (posterior part of the superior temporal gyrus) produces a modifying influence on caloric nystagmus namely a directional preponderance i.e a directional sensitivity towards the affected temporal lobe Evidence will emerge in this work that this LCA lies exactly where it is postulated to be and that it is an effector area. The consequences that follow in the study of these headaches will be seen to confirm this original assumption and postulation.

Thus the conception arises here that a minor subdued enduring epileptiform activity in say the left LCA, produces increased discharge activity in the right LB giving a PN on the right side i.e. in the right lateral position and minor vertiginous symptoms, which may be called episodic central positional vertigo with PN A further conception arises that if this disturbance occurs to a nearly equal extent in both LCAs then there will occur what may be called latent episodic central positional vertigo with bilateral PN (direction changing) The subject may then not admit that he is dizzy but may be shown to be unsteady in Romberg s test with eyes closed or in a Tandem Romberg test. The possible connections and interactions between this neuronic circuit and other parts of the nervous system need

is to be found in all the functional head aches *and many other conditions the ques* tion may be posed whether this is not a nor mal phenomenon and that an effort is being made to read some significance in it There is also an opinion expressed that nystagmus in the extreme limits of gaze is often present in normal persons in the erect position This apparently is not the view of other authori ties like Nylen (1950) and Schiller & Hed berg *(1960) who examine for a first-degree* PN and the latter comment that it is this type of PN that is usually found Even if it is true that some nystagmic jerks are to be found on extreme deviation of the eyes in normal persons (and in the positional test this alters to a brisk sustained non-fatigable nystagmus) then it will in fact become a PN In 3 cases out of the 100 studied here *there was a spontaneous nystagmus* on ex treme deviation of the eyes either to right or to the left In one case it was an ocular or pendular nystagmus and since the author was convinced despite the spontaneous nystagmus they exhibited that they had a PN and also unsteadiness etc they were accepted *and treated with successful results* In the two who had a vestibular type of spontaneous nystagmus the nystagmus also disappeared In the other 97 cases no nys tagmic twitch with extreme deviation of the eyes in the erect position was seen In all of them after a certain interference with the chorda tympani (CT) nerves the PN dis appeared and the headache ceased and did not recur Also it will be found that there are many situations in which this type of PN appears and disappears For instance this will be found to be so in the Vascular Headaches as has already been described in Chorda tympani neuralgia and Recurrent Parotitis *(Arulpragasam 1974 and 1967)*

The author (1967) studying Recurrent Par otitis and a rather rare syndrome of vertigo and salivary gland enlargement e g sub-mandibular gland enlargement usually with out a calculus came to the conclusion that there was a neuronic circuit which acted as some sort of feed-back mechanism to the labyrinth and also that if this circuit was disturbed by *an epileptiform process on one* side there was vertigo and a PN In this study there is a further confirmation of the existence of this neuronic circuit and con vincing evidence that the disturbance is an epileptiform one and that it occurs in the cerebral cortex The essential parts of this *circuit on each side* is a *Labyrinthine Corti* cal effector area (LCA) connecting by ef ferent fibres with the opposite side of the brain stem to a special labyrinthine nucleus which most likely is a part of the superior salivatory nucleus of the CT nerve Fibres continue from here with the other fibres of the *CT* nerve and *just as the nerve enters* the middle ear from the iter in the bone of the *posterior* wall (Fig 1) the labyrinthine branch (LB) is given off and courses medially under the mucosa of the posterior wall and hence cannot be seen Regarding this LB it will merely be stated that in the course of many hundred tympanotomies in the past eight years this LB has been seen on two *occasions* when it was abnormally and more anteriorly placed than usual The consistent and successful results of this study and the other evidence that emerges will constitute overwhelming confirmation and proof that there is a LB It would appear *useful to draw* attention to the findings of observers who

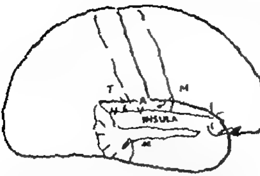

Fig. LCA. *T* taste area. *M* scalp muscle motor. *A* auditory sensory. *V* vestibular projection. It will become accepted that LCA extends onto the superior surface behind A to be contiguous with T. The area for nausea and vomiting is on the anterior part of the fascia at temporal lobe stem

have used the electron microscope and histochemical methods to detect the presence of nerve fibres showing acetylcholinesterase (AChE) activity in the non-acoustic and acoustic labyrinth of animals. Iurato et al. (1971) have shown efferent nerve fibres (unmyelinated) with AChE activity in the vestibular sensory areas of the chinchilla. In this species the efferent fibres appear to take a separate course from the brain stem along with the afferent fibres. Terayama & Yamamoto (1971) studying the olivo-cochlear bundle in the guinea pig, found efferent endings and preterminal fibres inside the organ of Corti and state that their relationship to the myelinated and unmyelinated efferent fibres outside the organ still remains unknown. It is here advanced that parasympathetic efferent nerve terminals are to be found in the human inner ear both non-acoustic and acoustic. The experimental investigations in animals would appear to speak in support of this view rather than controvert it. The work of Ishu (1971) in the rat appears to show that these fibres could not have found their way into the inner ear along the blood vessels though he found AChE activity in the stria vascularis and spiral ligament behind the external sulcus and the author here and elsewhere makes the serious claim that the LB to the CT is an anatomical entity.

Regarding these LCAs it will be postulated that they lie in the middle of the superior temporal gyrus of each side (Fig. 2). While there are many reasons for saying this, those of immediate concern are that they must be in close association with the cortical vestibular projection areas on each side which Behrman & Wyke (1958) after studying all the relevant evidence, conclude as extending forward from behind the primary acoustic area, to lie below and lateral to the latter in the superior temporal gyrus. There is also the reason that Carmichael et al. (1954) have shown that a destructive lesion in the posterior part of the temporal lobe (posterior part of the superior temporal gyrus) produces a modifying influence on caloric nystagmus, namely a directional preponderance, i.e. a directional sensitivity towards the affected temporal lobe. Evidence will emerge in this work that this LCA lies exactly where it is postulated to be, and that it is an *effector* area. The consequences that follow in the study of these headaches will be seen to confirm this original assumption and postulation.

Thus the *conception arises here* that a minor subdued enduring epileptiform activity in, say, the left LCA, produces *increased discharge* activity in the right LB giving a PN on the right side, i.e. in the right lateral position, and minor vertiginous symptoms, which may be called episodic central positional vertigo with PN. A *further* conception arises that if this disturbance occurs to a nearly equal extent in both LCAs *then there will* occur what may be called latent episodic central positional vertigo *with bilateral PN* (direction changing). The *subject* may then not admit that he is dizzy but may be shown to be unsteady in Romberg's test with eyes closed, or in a *Tandem Romberg test*. The possible connections and interactions between this neuronic circuit and other parts of the nervous system need

not be considered here and such as are necessary for the purposes of this thesis will become apparent and acceptable

Taste

The conception arose that when there is a central disturbance in the LB fibres of the CT nerve there would also be a significant delay in taste perception to chemical testing on the relevant part of the tongue This expectation has materialized to always be so *in fact Why only the taste pathways* are disturbed and not the other fibres in the nerve such as those for pain and secretomotor activity (the latter has not been studied) will become apparent from what is to follow
